It is important to note that in 2012, Kispersky and colleagues demonstrated in hippocampal slice preparations that O-LM cells do not fire preferentially at theta frequencies when injected with broadband artificial synaptic inputs but do phase-lock well to theta-modulated inputs. They also showed that O-LM phase-locking to theta frequencies was not due to h-currents (Kispersky et al. 2012). Therefore, the importance of O-LM cells for theta rhythm generation may not be as great as early models predicted. However, O-LM cells with their biophysical characteristics that include h-currents may predispose the system to phase-lock to high or low theta frequency inputs (Sekulić and Skinner 2017).

Theta/Gamma Models

A number of models that aim to gain insight into theta rhythm generation have also investigated the mechanisms involved in local hippocampal nested theta/gamma oscillations. These models have, in general, focused on three cell types: pyramidal cells, fast-spiking basket cells, and O-LM interneurons. They have investigated various

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 2 Schematics depicting the various network models used in Rotstein et al. (2005). Here, “O” represents their single-compartment oriens-lacunosum-moleculare (O-LM) cell model, which fires intrinsically at theta frequencies (12 Hz), and “I” represents their fast-spiking interneuron model. *Black filled circles*

represent inhibitory connections. (a) Two O cell models do not produce coherent theta oscillations. (b) A single I cell provides common inhibition to two connected O cells. Here, theta oscillations were coherent when I cell firings were at theta frequencies. (c) Robust and coherent theta oscillations were produced in a network of two O cells and an I cell with all-to-all connections

questions concerning the mechanisms underlying theta/gamma rhythm generation, and thus, due to the consideration of different issues, as well as the consideration of various underlying assumptions, the network models used differ.

We summarize these theta/gamma network models in Table 1. For simplicity, and as done by some authors, we use E, I, and O for models of pyramidal cells, fast-spiking interneurons, and O-LM cells, respectively. Unless otherwise noted, the I cell models used are from Wang and Buzsáki (1996). The O cell models used are comparatively presented elsewhere (► “[Hippocampus, Model Inhibitory Cells](#)”). The basis of the E cell models is given in footnotes. Connections included between different cell types are shown, but further specifics of their architecture are not described in the table. Here, we describe a few of these theta/gamma network models, and their experimental motivation, in more detail.

Wulff et al. (2009): Fast Inhibition onto Parvalbumin-Positive (PV+) Interneurons Is Required for Theta/Gamma Coupling

Rotstein et al. (2005) showed that their inhibitory network model required mutual connections between their O cells and their fast-spiking I cells for theta generation. To investigate this further, Wulff et al. (2009) employed both experimental techniques and computational modeling to determine the precise role of inhibition onto parvalbumin-positive (PV+) interneurons, of

which fast-spiking basket and axo-axonic interneurons make up the majority (~75% collectively; Baude et al. 2007). First, they genetically modified mice in which fast GABA_A receptor-mediated inhibition was removed from PV+ interneurons and found that theta oscillation and theta/gamma oscillation coupling in vivo were dependent on this synaptic input. Second, they created a mathematical network model to determine if these changes to theta and theta/gamma coupling were due to ablated connections within an intra-hippocampal theta-generating network.

Their network model consisted of a single E cell, I cell, and O cell (see Fig. 3a and Table 1), where the O cell was representative of a cell that preferentially spikes at theta frequency, but not necessarily an O-LM interneuron. The E cell was representative of a population of pyramidal cells and thus fired intrinsically at the population frequency (i.e., gamma). As with the model in Rotstein et al. (2005), the $O \leftrightarrow I$ network produced theta oscillations. In addition, gamma was generated through a mechanism involving the $E \leftrightarrow I$ network (pyramidal-interneuron network gamma or PING. ► “[Hippocampal Oscillations, Mechanisms \(PING, ING, Sparse\)](#)”). To mimic their experimental protocol, they removed the inhibitory synapses onto the I cell (by setting the maximal synaptic conductance strength of the $O \rightarrow I$ and the $I \rightarrow I$ connections to zero) (Fig. 3b). Consistent with their experimental results, without these fast inhibitory synapses,

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 3 A schematic of the network model in Wulff et al. (2009). Their network model consisted of one excitatory cell model (*E*), five fast-firing inhibitory cell models (*I*), and 15 models of cells that spike preferentially at theta frequencies (*O*). *Black filled circles* represent inhibitory connections, and *black filled triangles* represent excitatory connections. (a) The Wulff et al. (2009) theta-gamma-generating network model had all-

to-all connections among the cell populations, as well as recurrent connections among the I cell population. (b) To mimic their experimental protocol, where GABAergic synapses onto fast-spiking interneurons were ablated, they set their O–I and I–I connection strengths to zero. Here, they observed attenuated theta oscillations and a reduction in the modulation of gamma amplitude and frequency by theta

their network model had attenuated theta oscillations and a large reduction in gamma amplitude and frequency modulation by the theta phase. Thus, their model implicates an intra-hippocampal network as responsible for the reduced theta and theta/gamma coupling seen in their genetically modified mice.

Gloveli et al. (2005) and Tort et al. (2007): O-LM Cell Morphology Affects Theta/Gamma Rhythms Across the Longitudinal Axis

Andersen et al. (1971) showed that the hippocampus is composed of multiple laminae that are arranged in parallel across the longitudinal axis, indicating that there may be multiple functional units organized across this axis. It is possible that, due to the diversity of interneuron types, a particular class may have the appropriate axonal arbor to serve as a connection between these distinct segments. Experimental and modeling work suggests that O-LM cells may comprise a critical component of local hippocampal theta oscillations (Maccaferri and McBain 1996; Gillies et al. 2002; Rotstein et al. 2005). Gloveli et al. (2005) investigated this possibility by examining the axonal arborization of biocytin-filled O-LM cells in the CA3 region of the hippocampus and found that these cells branched most extensively in the longitudinal direction. In fact, they formed clusters across this axis, indicating that they may serve to connect distinct functional units. Gloveli et al. (2005) also determined that gamma was the dominant field network activity in the CA3 of transverse slices, theta was predominant in longitudinal slices, and theta and gamma were both clearly present in coronal slices. Thus, they created a network model to determine whether the distinct longitudinal trajectory of O-LM cell axons could explain this difference in network oscillation generation in the various slice preparations.

As Rotstein et al. (2005) proposed that both O-LM cells and fast-spiking interneurons were required for network theta oscillations, and Ermentrout and Kopell (1998) suggested that pyramidal cells may also be necessary for gamma oscillations (► “Hippocampal Oscillations, Mechanisms (PING, ING, Sparse)”),

Gloveli et al. (2005) created a network model of two O-LM cell models (O), two fast-spiking interneuron models (I), and a single two-compartment (one somatic and one dendritic compartment) pyramidal cell model (E) (as in the network in Fig. 3a), where the O cell model was connected to the dendritic compartment of the E cell model and the I cell model was connected to the somatic compartment of the E cell model. The O-LM cell model was adapted from Saraga et al. (2003), included an h-current, and fired spontaneously at approximately 10 Hz. To model the transverse slice, synaptic connections from E cells were stronger than in the model longitudinal slice (Fig. 4a). This was done to reflect the transverse distribution of pyramidal cell axon collaterals. Conversely, in the model longitudinal slice, synaptic connections from O cells were stronger than in transverse slices to reflect the longitudinal organization of O-LM axon collaterals (Fig. 4b). In the model coronal slices, the synaptic connections had strengths in between those of the longitudinal and transverse slices.

The Gloveli et al. (2005) network model used the non-spiking dendritic compartment of their E cell model to compare with their experimental network oscillations. Similar to what they found experimentally, their model coronal slices produced theta-modulated gamma. Here, the gamma synchrony was produced by the E and I cell interactions (► “Hippocampal Oscillations, Mechanisms (PING, ING, Sparse)”). E and I fired synchronously, but in order to do so, the E cell was required to fire at gamma frequencies. Theta modulation required O-LM cells to fire at theta frequencies and required connections between O and I cells (as in Rotstein et al. 2005). In the model longitudinal slice, all cells fired at theta frequencies due to the strong theta-modulated input from O-LM cells. In the model transverse slice, E and I were synchronized at gamma frequencies, and O remained firing at theta, due to the weak O-LM cell inputs. They noted, however, that these results may be specific for CA3, as CA1 O-LM cells have been shown to extend along both the transverse and longitudinal axes (Sik et al. 1995).

Based on the hypothesis that O-LM cells could connect distinct functional units across the

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 4 A schematic of the (a) transverse and (b) longitudinal network models in Gloveli et al. (2005). The model networks were represented by a two-compartment excitatory cell model (E), two fast-spiking inhibitory cell models (I), and two O-LM cell models (O). Black filled circles represent inhibitory connections, and black filled triangles represent excitatory connections. Thick (thin) black lines represent connection strengths

that were increased (decreased) to mimic the different slice configurations. (a) In the network model representing the transverse hippocampal slice, E–O and E–I connections were stronger, and connections from the O cell were weaker, than in the longitudinal slice model. (b) In the network model of the longitudinal slice, synaptic connections originating from the E cells were weaker, and those from the O cells were stronger, than in the transverse slice model

H

longitudinal axis, Tort et al. (2007) created a network model to investigate whether O-LM cells could coordinate multiple cell assemblies. To do so, they created “modules” of networks similar to those of Gloveli et al. (2005) (but with some changes, such as a five-compartment E cell model and a larger network size). The model local field potential (LFP) of each module was set to be the membrane potential of a “passive” pyramidal cell model (an E cell model that did not spike due to the absence of an external drive current). Each module was then connected to a neighboring module through O cell connections to distal E cell compartments (representing the longitudinal distribution of the O-LM cell projections) (Fig. 5). Tort et al. (2007) found that each module produced theta-modulated gamma firing in a functionally similar manner to Gloveli et al.’s (2005) model: the I and E cells produced synchronized gamma firing (► “[Hippocampal Oscillations, Mechanisms \(PING, ING, Sparse\)](#)”), and the O cell models fired in clusters at theta frequencies. Through across-module O to E cell connections, multiple gamma assemblies could be formed. Modules would synchronize with each other when a subset of their cells received a similar drive, as long as each module exhibits PING (requiring E cells to receive enough drive to fire at

least as fast as I cells). Thus, Tort et al. (2007) propose that O-LM cells in the CA3 region can bring about gamma synchronization of distinct modules along the longitudinal axis.

Orbán et al. (2006): The Effect of Hyperpolarization-Activated (h) Currents in Pyramidal and O-LM Interneurons on Theta/Gamma Generation

Gillies et al. (2002) implicated O-LM interneurons, and specifically their h-currents, as a critical component of a pharmacologically induced CA1 theta oscillation in slice preparations. Indeed, theta oscillations in this experimental model were sensitive to blockade of h-currents (Gillies et al. 2002). Since then, h-currents have been incorporated as an essential part of O cell models in networks of hippocampal theta and theta/gamma generation (e.g., Rotstein et al. 2005; Gloveli et al. 2005). However, h-currents also exist in pyramidal cells, where it is tonically active at resting membrane potentials (Magee 1998). In addition, for depolarized membrane potentials, pyramidal cells have intrinsic resonant properties at the theta frequency (Strata 1998). Thus, Orbán et al. (2006) created a network model to determine whether h-channel activation could pace theta oscillations in the hippocampus, and compared

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 5 A schematic of the network model from Tort et al. (2007). Tort et al. (2007) created “modules,” where each module consisted of a network of models representing O-LM cells (*O*), excitatory cells (*E*), and fast-spiking interneurons (*I*). Two modules are shown

in the schematic. Each module was connected through O–E connections, representing the longitudinal distribution of O-LM cell projections. *Black filled circles* represent inhibitory connections, and *black filled triangles* represent excitatory connections

Hippocampal Theta, Gamma, and Theta/Gamma Network Models, Fig. 6 A schematic of the network model in Orbán et al. (2006). Their network model consisted of 15 excitatory cell models (*E*), 100 fast-spiking inhibitor cell models (*I*), and 70 O-LM cell models (*O*). *Black filled circles* represent inhibitory connections, and *black filled triangles* represent excitatory connections. Unlike previous hippocampal theta-/gamma-generating network models, they did not include an I–O connection

h-current activation in *E* and *O* cells to determine how they affected theta/gamma rhythms.

Orbán et al. (2006) created a network model consisting of *E*, *O*, and *I* cells (Fig. 6). In contrast with other theta/gamma models, they did not include a synaptic connection from *I* to *O* cells

and used a detailed 256-compartment model with h-current dynamics to represent the *E* cells. They used their model to study the components necessary for theta generation and explored the effects of interactions between individual neuron populations. They found that *I* to *O* cell connections were not necessary for theta/gamma generation, although they may have an effect on the stability of the oscillation. Constant depolarizing current injected into *E* cells increased the field frequency; however, it was only slightly affected when they did so with *O* cells. In addition, eliminating h-currents in both *E* and *O* cells caused theta frequency modulation of neuronal populations to disappear. However, reducing the maximal conductance strength of h-channels in *O* cells did not reduce theta amplitude, whereas blocking these channels in *E* cells resulted in a large decrease in theta amplitude. Thus, Orbán et al. (2006) have implicated pyramidal cell h-currents, rather than O-LM cell h-currents, as an important component to hippocampal theta oscillations and have indicated that potential connections from O-LM cells to fast-firing interneurons do not play a critical role.

There are a few hippocampal theta-/gamma-generating network models that we have not described in detail above (see Table 1) but are

briefly described here. White et al. (2000) investigated whether slow GABAergic synapses, generated by a distinct group of interneurons, could be responsible for the slow theta rhythmicity. Tiesinga et al. (2001) used E cell model networks (which occasionally included I cells) to examine the known physiological effects of carbachol on the muscarinic and calcium-dependent potassium currents of pyramidal cells and on the strengths of excitatory postsynaptic potentials. Finally, Neymotin et al. (2011) used a 1200 cell network of E, I, and O cells to investigate the effects of ketamine (an *N*-methyl-D-aspartate receptor, or NMDAR, antagonist) on CA3 theta/gamma rhythms. Although they primarily used extrinsic inputs to pace the theta oscillations, they found that their hippocampal network could produce intrinsic theta/gamma oscillations when this external drive was removed and that connections between O and I cells were not required for this internally generated rhythm. Furthermore, they found that the experimental effect of ketamine on theta/gamma rhythms could only be reproduced in the model with the reduction of NMDAR in their O cells. Thus, their network model predicted that NMDARs in O-LM interneurons play an important role in ketamine effects on theta/gamma oscillations, and the authors suggested that this effect may be reversed with a continuous inward current to these cells (Neymotin et al. 2011).

Overall, theta-/gamma-generating network models have focused on the dynamics between O-LM interneurons, fast-spiking interneurons, and pyramidal cells. However, the critical components required for these models have not been settled upon: the connectivity of these cell types and the role of particular ion channels remain unclear. Further experimental and modeling studies should be done to address these issues.

Models for an Intrinsic Theta Rhythm Experimental Context

It has been shown that theta and theta/gamma rhythms can spontaneously emerge in an intact whole hippocampus preparation *in vitro* (Goutagny et al. 2009; Jackson et al. 2011). This

implies that rhythmic drive to the hippocampus is not necessary for the hippocampus to exhibit rhythmic output. Network models based on this whole hippocampus preparation have been developed (Bezaire et al. 2016; Ferguson et al. 2017). Ferguson et al. (2017) used single-compartment Izhikevich-type cellular models with explicit links to the data for the pyramidal (E) cells and fast-firing inhibitory (I) cells (Ferguson et al. 2013, 2015b). They showed that the essence of the intrinsic theta rhythm generation in CA1 hippocampus occurred in E-I networks in which the pyramidal cells were minimally connected, and there was spike frequency adaptation and post-inhibitory rebound in the pyramidal cells. The more detailed network CA1 microcircuit model of Bezaire et al. (2016) had eight types of inhibitory cells and pyramidal cells with multi-compartment representations, and network connectivity and cellular specifics were based on an extensive knowledge base of the experimental data (Bezaire and Soltesz 2013). The full-scale CA1 microcircuit model exhibited theta and theta/gamma rhythms.

Related (Theta/Gamma) Models and Further Considerations

Experimental work has suggested that synchronization of theta oscillations in the hippocampus is brought about by a primarily extrinsic mechanism, since, for example, septal neurons fire in synchrony with hippocampal theta, and lesions to the medial septum significantly decrease the amplitude of theta oscillations (Petsche et al. 1962; Buzsáki 2002). Thus, some investigate theta modulation, and not generation, of hippocampal circuits. These models incorporate an external drive (from, e.g., the medial septum or the entorhinal cortex) to pace the hippocampal rhythm (e.g., Kunec et al. 2005; Cutsuridis et al. 2010; Cutsuridis and Hasselmo 2012; Pastoll et al. 2013). Theta inputs via non-extrinsic inputs have also been investigated, and these models showed that distally projecting inhibitory cells could control the power of theta rhythms (Chatzikalymniou and Skinner 2018; Ferguson et al. 2015a). Network models may also examine theta/gamma modulation in using non-

biophysically motivated cell models. For example, Pastoll et al. (2013) created a network of integrate-and-fire neurons, where each model received an external current source (composed of the sum of constant background activation, theta-modulated current, velocity modulation current, and hippocampal place field input) to create an attractor network model.

In conclusion, many theta and theta/gamma network models exist, and mechanisms for their generation are beginning to emerge. However, more work is needed for us to obtain a complete understanding of how theta and theta/gamma oscillations in the hippocampus are produced.

Definition

Hippocampome.org is a freely accessible, comprehensive knowledge base of neuron types in the rodent hippocampal formation (dentate gyrus (DG), CA3, CA2, CA1, subiculum (Sub), entorhinal cortex (EC)) (Wheeler et al. 2015). Built upon extensive data mining of scientific literature, neuron types are discriminated by their primary neurotransmitters, axonal and dendritic patterns, synaptic specificity, electrophysiology, and molecular markers. All annotated properties are individually supported by specific evidence in peer-reviewed publications. Hippocampome.org is the basis for a probabilistic atlas of the entire synaptic blueprint of the rodent hippocampus (Ascoli 2010).

Detailed Description

Hippocampome.org is a powerful, groundbreaking resource of knowledge, distilled from hundreds of scientific articles and integrated

into a framework of morphologically defined neuron types. Hippocampome.org distinguishes well over 100 neuron types, which are defined in part by their axonal and dendritic expanse into the 26 cytoarchitectural parcels of the hippocampal formation: DG outer stratum (s.) molecular, inner s. molecular, s. granulosum, hilus; CA3 s. lacunosum-molecular, s. radiatum, s. lucidum (SL), s. pyramidale (SP), and s. oriens; 4 each in CA2 and CA1 (same as CA3 except SL); Sub s. molecular, SP, polymorphic layer; and EC layers I–VI. For these neuron types, the annotated evidence supports well over 10,000 distinct “pieces of knowledge” regarding not only the presence or absence of their axons or dendrites within any of the 26 parcels, but also the expression or non-expression of molecular markers, including data leveraged from the Allen Brain Atlas (Hamilton et al. 2017b), individual electrophysiological properties, and known and potential connectivity (Rees et al. 2016).

All of the accumulated and collated knowledge of these neuronal properties are fully browsable and searchable. In browse mode, Hippocampome.org provides summaries of its information in the form of fully clickable matrices. Searching for neuron types is accomplished through selections from dynamically updated pull-down menus of any of the annotated properties, and compound queries can be crafted with AND & OR Boolean connectors. Searches can also be conducted using PubMed identifiers, author names, neuron names/synonyms, original firing patterns, and neuron terms (Hamilton et al. 2017a). Returned results contain full bibliographic information, a link to the article with a pointer to the specific evidence location within, and a list of neuron types with information from the article.

The human- and machine-readable knowledge contained in Hippocampome.org will be leveraged to formulate a detailed computational model of the entire rodent hippocampal formation. Computer simulations will initially involve the simplified formalism of Izhikevich models and parameters (Venkadesh et al. 2018). The simulations also will leverage information such as firing pattern

phenotypes (Komendantov et al. 2018), neurite lengths, and neuron type counts to fill in the details of the model. As technology advances and computing power continues to increase, more biophysically detailed modeling will become feasible. In conjunction with the growth in simulation complexity, Hippocampome.org will continue to expand its compendium of openly shared, annotated knowledge and help to advance the bounds of neuroinformatics as a whole.

Definition

Hippocampus, model excitatory cells refer to mathematical models of neurons that are designed to represent excitatory neurons in hippocampus. Here, we focus on biophysically motivated

models of excitatory cells in the hippocampus proper (specifically the CA1 and CA3 pyramidal cells) and the granule cells of the dentate gyrus (DG). This article discusses some common motives for constructing these models and describes a few frequently used models in more detail.

Detailed Description

Introduction

Three principal hippocampal excitatory cell types are CA1 pyramidal cells, CA3 pyramidal cells, and granule cells of the DG (Fig. 1). These cells depolarize their postsynaptic targets through glutamatergic transmission of three main types of ionotropic receptors: α -amino-3-hydroxy-5-methyl-isoxazole-propionic acid (AMPA), kainate, and *N*-methyl-d-aspartate (NMDA). This is in contrast to hippocampal interneurons, which inhibit their postsynaptic targets through

γ -aminobutyric acid (GABA) receptors (for inhibitory cell models, see ► “[Hippocampus, Model Inhibitory Cells](#)”). We note that hilar mossy cells also excite their postsynaptic targets, but due to the lack of experimental characterization of these cells relative to the other three cell types and the fact that very few models of these cells exist, we do not discuss them in this article.

Why Do We Care About Hippocampal Excitatory Cells?

Much of our general knowledge about neuron structure and function is derived from studies of excitatory cells in the hippocampus. This is most notably true because the hippocampus has a structured architecture, where principal cell bodies lie in a single layer, and dendritic trees and axonal projections compose well-defined laminae (Fig. 2). These organized layers create identifiable current sinks and sources, which facilitate extracellular recordings of local field rhythms in both *in vivo* and *in vitro* preparations. In addition, the predictable location of principal cell bodies simplifies the identification process for intracellular recordings. Excitatory axonal projections between hippocampal regions are constrained within these laminae (e.g., Schaffer collaterals from CA3 to CA1 are located in the stratum radiatum and stratum

oriens), providing a means to stimulate principal cells to study synaptic transmission, integration, and plasticity. Indeed, long-term potentiation (LTP) was discovered in the dentate gyrus (DG) of the hippocampus (Lømo 1966), and most recent LTP studies have taken place in the CA1 region. The hippocampus is known to play an important role in learning and memory, and thus understanding synaptic plasticity as a mechanism of these processes is essential. Furthermore, the hippocampus, and principal cell activity, have been implicated in playing a large role in a number of neurological diseases, such as epilepsy and Alzheimer’s (Bruton 1988; Braak and Braak 1991). Finally, experimental work in this area is also facilitated because *in vitro* hippocampal slice preparations can remain alive and healthy for extended periods, permitting lengthy recordings of this easily accessible neuronal activity.

CA1 pyramidal cells, CA3 pyramidal cells, and DG granule cells comprise the majority of the neurons in their respective regions, and thus excitatory cell activity is likely to strongly influence local network rhythms. Understanding excitatory cell activity may provide insight into the mechanisms underlying the generation of behavior-dependent local field oscillations, which are thought to play an essential role in

Hippocampus, Model Excitatory Cells, Fig. 2 A schematic showing the structured organization of the hippocampus, with principal cell bodies restricted to particular laminae. (a) Pyramidal cells of the CA1, CA2, and CA3 area. Cell bodies lie in the stratum pyramidale. (b) Cell bodies of dentate granule cells lie in the stratum

granulosum. (With kind permission from Springer Science+Business Media: *Hippocampal Microcircuits* (Cutsuridis, V., Graham, B., Cobb, S. & Vida, I., eds.), Part I, Chapter 2, 2010, p. 27–67, I. Vida, “Morphology of Hippocampal Neurons,” Fig. 2A, C)

many aspects of learning and memory, such as feature binding, temporal encoding, and spatial navigation (Buzsaki 2002; Colgin and Moser 2010).

Overall, the vast number of studies involving hippocampal excitatory cells has furthered our understanding of intrinsic cell functioning, synaptic transmission, synaptic integration, synaptic plasticity, network oscillations, and the role of neural activity in behavior and disease. This plethora of knowledge provides an excellent platform to build well-constrained models to address a variety of questions about cell functioning.

Why Build Hippocampal Excitatory Cell Models?

Hippocampal excitatory cell models allow us to systematically explore a specific question in a simplified setting. In many cases, these questions are difficult or impossible to fully explore experimentally. For example, Vetter et al. (2001) explored the effect of morphology on action potential propagation. By building multi-compartment models from three-dimensional reconstructions of rat CA1/CA3 pyramidal cells and DG granule cells (among others) and by using the same active and passive ion conductances across cell models, they were able to isolate the effects of dendritic morphology on the efficacy of signal propagation. Another feature that is more easily explored in models than in experiment is how the distribution of ion channels across the neuron affects its activity (e.g., Hoffman et al. 1997). One can explore the role of specific synaptic or intrinsic properties on spiking patterns (such as bursting, adaptation, after-depolarizing potentials, etc.) through mathematical models (e.g., Traub and Llinás 1979; Traub 1982; Warman et al. 1994; Pinsky and Rinzel 1994) or investigate how the activation of particular ion channels shapes the efficacy or weight of postsynaptic signals (e.g., Lipowsky et al. 1996). Models can also be used to study passive cable properties (e.g., Major et al. 1994; Schmidt-Hieber et al. 2007; Baker et al. 2011). In addition, excitatory cell models can be used to study the role of principal cells in network oscillations (e.g., Gloveli et al. 2005). Therefore, models can help us understand

cellular and network mechanisms and guide future experiments. Their power lies in their predictive capabilities and the generation of hypotheses.

How Do We Model These Excitatory Cells?

How one constructs a neuron model depends on the question at hand and on the availability of experimental data. For details of different approaches to constructing neuron models, see articles referenced in the “Further Reading” section. In general, neuron models can be divided into three categories based on their level of biological abstraction: rate-based models, simple spiking models, and biophysical models. Rate-based models are the simplest of the three and describe a cell by its firing rate as a function of time (e.g., Wilson and Cowan 1972). As these models are constructed based on the firing rate alone, they will not be discussed in this article.

Spiking models focus on representing the firing behavior of the neuron. Although some spiking models rely on a simple threshold method, such as the leaky integrate-and-fire model (see “Integrate and Fire Models, Deterministic”), others aim to reproduce more complex firing patterns (e.g., Izhikevich 2003). Thus, in choosing a spiking model, one must determine the amount of desired computational efficiency, as well as the key properties of the neuron that one wishes to capture (e.g., the frequency-current profile, bursting, adaptation, spike shape). The computational and mathematical simplicity of these spiking models makes them good candidates for examining network dynamics (e.g., Dur-e-Ahmad et al. 2012).

Biophysical models describe the dynamics of a cell’s membrane potential, where the cell’s ion channels are represented by conductances, and the cell’s lipid bilayer through a capacitor (see Skinner 2006 for more details). These models can vary greatly in the level of detail incorporated, and choices about the model’s complexity will depend on the question being addressed. For example, if one is investigating how ion channel properties on oblique dendrites affect cell activity (e.g., Migliore et al. 2005), one would require a multi-compartment model that represents a cell’s

detailed morphology. Of course, the dynamics and distribution of every receptor and ion channel type involved in hippocampal excitatory cell functioning are not known. Therefore, choices must be made as to which channels to include, how to constrain their kinetics, and how they are distributed. However, in other cases when computational efficiency and simple dynamics are prioritized to facilitate analyses or to construct large networks, one may prefer to use a simpler single-compartment model. Therefore, before constructing a neuron model, a number of difficult choices must be made.

Due to the abundance of experimental data that currently exists for hippocampal excitatory cells and the large number of experimental questions that remain, many different models of these cells have been created (e.g., see ModelDB: <http://senselab.med.yale.edu/modeldb/FindByRegionList.asp>). Many models are created by expanding or reducing existing models or are derived based on properties from multiple models. Therefore, instead of attempting to address every model, we will highlight a few of the commonly used ones and the various questions they have helped address.

CA1 Pyramidal Cell Models

CA1 pyramidal neurons are arguably the most studied class of neuron in the brain, both functionally and structurally. It is generally easier to keep these cells healthy in slice preparations than those in the adjacent CA3 area, which contributes to the vast number of recordings from this area (Spruston and McBain 2007). The structurally homogeneous Schaffer collateral inputs from CA3 to CA1 provide a pathway that is easily stimulated to investigate synaptic activation and plasticity in CA1 pyramidal cells. In addition, these neurons have relatively large primary apical dendrites (Fig. 2a), which permit dendritic patch-clamp recordings. Thus, studies of CA1 pyramidal cells have increased our understanding of principal cell functioning in many ways.

Due to the large amount of research focused on CA1 pyramidal cells, they provide a great starting

point at which models can be used to investigate specific questions about how certain properties affect cell functioning. Thus, many of the commonly used CA1 pyramidal cell models are detailed multi-compartment biophysical models. However, simple models have also been constructed to explore cellular and network dynamics with computational ease (e.g., Ferguson and Campbell 2009). Many different questions have been addressed with CA1 pyramidal models, such as how different active ionic conductances influence spike shape and firing properties (e.g., Traub and Llinás 1979; Warman et al. 1994), and the role of particular axonal ion channels in action potential initiation (e.g., Royeck et al. 2008).

We discuss three models here that are used to explore: (1) the effects of channel distribution on cell activity, (2) how synaptic signals are integrated, and (3) how channel dynamics and oblique dendrites interact to affect action potential propagation.

Hoffman et al. (1997): Effects of K-A Distribution on Action Potential Generation and Excitatory Post-synaptic Potential Shape

Through a series of somatic and apical dendritic patch-clamp recordings, along with the use of a variety of channel blockers, Hoffman et al. (1997) revealed that CA1 pyramidal cell dendrites contain a high density of transient A-type potassium ion channels (K-A). This increased density was shown to prevent action potential generation in the dendrites, to limit the amplitude of back-propagating action potentials, and to reduce excitatory postsynaptic potentials (EPSPs). Hoffman et al. (1997) created a CA1 pyramidal model to investigate how an increased density of K-A channels in the dendrites may interact with other ion channels to produce these features.

A reconstruction of a hippocampal pyramidal neuron was used to construct the morphology of the pyramidal cell model. They chose to include only sodium channels (Na), delayed rectifier potassium channels (K-DR), and two K-A channels: a proximal channel used within 100 μm from the soma and a distal channel for distances greater than 100 μm from the soma. While the Na and K-DR channels were distributed uniformly

throughout the soma and dendrites of the neuron model (and increased tenfold in the axon), the peak conductance strength for both K-A channels increased with distance from the soma. The Na and K-A conductances were set to reproduce their experimentally determined K-A to Na ratio of ~3:1, whereas their K-DR conductance was set to repolarize the action potential in the absence of K-A channels. Since one can easily change the distribution and strength of ion channels in a neuron model, this computational modeling approach allowed them to investigate how this experimentally determined distribution of K-A channels affects action potential amplitude and EPSP propagation toward the soma.

The authors found that by incorporating K-A channels in their model, their experimental findings were reproduced: somatic action potentials were generated, they decreased as they propagated toward the dendrites, and EPSP amplitudes were reduced. Interestingly, by pairing simulated EPSPs onto a single branch with a back-propagating action potential, they showed that action potential amplitude was significantly boosted in the branch receiving the input. This occurred because K-A channels are susceptible to rapid depolarization-induced inactivation during subthreshold input. This inactivation allowed an increase in Na activation, which boosted the amplitude of the action potential. Through this mechanism, the propagation of action potentials into specific branches of the dendritic tree may be regulated by synaptic inputs and may thereby play a role in synaptic plasticity.

Poirazi et al. (2003): Rules of Synaptic Integration

Conflicting reports of synaptic integration rules have brought into question how pyramidal cells process information (e.g., Nettleton and Spain 2000; Cash and Yuste 1999). Poirazi et al. (2003) built a computational model to assess whether arithmetic summation in CA1 pyramidal cells is best represented by linear or nonlinear integration rules. They also set out to determine whether particular aspects of experimental design may have contributed to the conflicting reports. Computational modeling provided an ideal forum

to answer these questions, as they could precisely control the number, location, and types of synapses, and record the postsynaptic responses from any location on the model neuron simultaneously.

In this highly detailed model, Poirazi et al. (2003) used a reconstructed CA1 pyramidal cell to create the morphology of the model neuron (consisting of 183 compartments) and included 17 different ion channels (leak, somatic/axonic sodium, dendritic sodium, somatic/axonic delayed rectifier potassium (K-DR), dendritic K-DR, proximal A-type potassium (K-A), distal K-A, M-type potassium, a mixed conductance hyperpolarization-activated channel, T-type calcium, somatic R-type calcium (Ca-R), dendritic Ca-R, somatic L-type calcium (Ca-L), dendritic Ca-L, slow calcium-dependent potassium (K-AHP), medium K-AHP, and persistent sodium) and four types of synapses (AMPA, NMDA, GABA_A, GABA_B). Where possible, channel kinetics were taken from studies where individual channel properties, such as activation and inactivation curves, time constants, and location-dependent densities, were investigated (e.g., K-A dynamics from Hoffman et al. 1997). In addition, they validated their model with a number of tests to ensure that it produced output similar to that observed experimentally. For example, they tested the effect of the hyperpolarization-activated mixed cation current (h current) on input resistance and steady state voltage propagation and compared with the results from Magee et al. (1998).

The authors simultaneously recorded from the soma and dendrites of the neuron model. They compared their results using two different response measures, two different stimulus protocols, and two different spatial integration conditions. They found that the neuron's response to paired inputs was well described by the sum of nonlinear subunit responses, where the subunit response represents that of the dendritic branches. They also suggested a number of ways in which experimental design choices may influence one's conclusions regarding synaptic integration rules.

Many subsequent studies have either used this model or a modified version of it (e.g., Cutsuridis et al. 2010; Dyhrfeld-Johnsen et al. 2008). Other

studies have used properties of this model to create their own models (e.g., Narayanan and Johnston 2007; Bianchi et al. 2012; Ashhad and Narayanan 2013).

Migliore et al. (2005): Action Potential Propagation Into/from Oblique Dendrites

Hoffman et al. (1997) demonstrated that A-type potassium (K-A) channel densities increased in the primary apical dendrites of CA1 pyramidal cells, and through calcium-imaging experiments. Frick et al. (2003) suggested that the density of these channels may be especially high in oblique apical dendrites. However, the precise biophysics of K-A currents in the oblique dendrites remained unclear. More specifically, the effects of the morphology of oblique dendrites (i.e., the geometry at branch point, the distance from the soma, etc.), in combination with dendritic K-A channel properties, on action potential propagation into and from oblique dendrites were not well understood. As CA1 pyramidal cell oblique dendrites comprise the majority of apical tree surface area and are the main target of CA3 Schaffer collaterals, their functional role in shaping neural activity is important to understand. However, these dendrites are very thin, and thus it is very difficult to record their electrical properties. Thus, this problem is best addressed with computational modeling, as multiple morphologies and dendritic distributions of K-A channels can be easily explored.

Migliore et al. (2005) used 27 reconstructed three-dimensional morphologies of rat CA1 pyramidal cells. The same uniform passive properties were used for all neurons. They included four channel types: sodium (Na), delayed rectifier potassium (K-DR), K-A, and hyperpolarization-activated h. Na and K-DR were distributed uniformly over the entire basal and apical dendritic tree. However, because the K-A and h distributions in oblique dendrites have not been characterized experimentally, their peak conductances were distributed in the model in three separate ways. In the first set of simulations, K-A and h peak conductances were increased linearly across the whole dendritic tree. In the second, K-A and h peak conductances increased in the main apical trunk, but were set to be constant (and were

determined by the value at the point of attachment to the main trunk) in the rest of the dendritic tree. In the final case, h peak conductance was increased linearly across the dendritic tree (as in the first case), but K-A peak conductance was increased threefold in each oblique with respect to its value at the point of attachment.

They found that individual oblique dendrites regulated local action potential forward and backward propagation. The local morphology of the obliques had the most effect on forward propagation, whereas the distribution of K-A channels influenced backward action potential propagation the most. They also found that somatically generated action potentials propagating toward the dendrites invade the oblique branches in an all-or-none fashion. This process was highly regulated by local K-A distributions. In fact, their model predicted that the distribution of h and K-A channels in the oblique dendrites can even affect the antidromic propagation of action potentials into the main apical shaft. However, an increase in h channels would facilitate action potential back propagation, whereas an increase in K-A channels would impede it. Overall, their model showed that signal propagation in CA1 pyramidal cells would be greatly affected by the morphology of their oblique dendrites, as well as their K-A and h channel distributions along them.

CA3 Pyramidal Cell Models

Although the properties and distributions of voltage-gated channels have been reasonably well characterized in CA1 pyramidal cells, less is known about those in CA3. One of the contributing factors to this is that CA3 pyramidal apical dendrites bifurcate closer to the stratum pyramidale and therefore lack the significant primary apical dendrite found in CA1 pyramidal cells (Spruston and McBain 2007) (Fig. 2b). As a result, CA3 pyramidal cell models are more theory driven than those of CA1. Due to the lack of experimental data compared with CA1 pyramidal cells, particular channel kinetics of CA3 pyramidal cell models are occasionally derived from CA1 pyramidal cells (e.g., Baker and Olds 2007;

Hemond et al. 2008), and the focus of many CA3 pyramidal models is on cell firing patterns (e.g., Traub 1982; Traub et al. 1991; Migliore et al. 1995; Hemond et al. 2008). CA3 pyramidal cell models have been adapted directly from CA1 pyramidal cell models (e.g., Tort et al. 2007 based on a reduction of Migliore et al. 2004), and general pyramidal cell models have been constructed based on properties and morphologies of both CA1 and CA3 pyramidal cells (e.g., Jaffe et al. 1994).

One of the major differences between CA1 and CA3 pyramidal cells is their network configuration. CA1 pyramidal cells form very few recurrent connections (~1%) (Knowles and Schwartzkroin 1981; Deuchars and Thomson 1996), whereas CA3 pyramidal cells are highly interconnected (Amaral and Witter 1989; Amaral et al. 1990). Thus, some network models use one type of pyramidal cell model for both CA1 and CA3 networks and alter only the number of recurrent connections among the neurons in each region (e.g., Taxis et al. 2012). However, CA1 and CA3 pyramidal cells do have some difference in their firing profiles and intrinsic properties, and these differences may be important depending on the question being investigated. For example, bursting is more prominent in CA3 pyramidal cells (Schwartzkroin 1978; Wong and Prince 1978), and their membrane time constant is considerably slower (Spruston and Johnston 1992). Here, we discuss in more detail a few models that are built to further our understanding of the mechanisms involved in CA3 pyramidal cell firing patterns.

Traub et al. (1991): Firing Patterns

Traub et al. (1991) set out to create a model that captured the electrical properties of a CA3 pyramidal cell, aiming to provide insight into the mechanisms underlying its complex firing patterns. Their group had previously constructed a CA3 pyramidal cell model that produced bursting and spiking patterns similar to those recorded experimentally (Traub 1982). However, in contrast with CA3 pyramidal cell recordings *in vitro* (Wong and Prince 1981), their 1982 model was not able to switch from repetitive bursting to repetitive single action potentials with increased

depolarization. In addition, under certain conditions, network models built with their pyramidal cell model were expected to produce synchronized multiple bursts, but did not unless some ad hoc properties of the synapses or axons were assumed (Traub et al. 1984). Traub's group hypothesized that these failures could be because the model was unable to generate dendritic calcium spikes. This, along with new data from whole-cell and calcium-imaging experiments (Kay and Wong 1986; Regehr et al. 1989), motivated the authors to construct a new CA3 pyramidal cell model. They aimed to understand the conditions under which this cell might switch between modes of firing, and to determine the essential properties for the synchronization of multiple bursts in a network of CA3 pyramidal cells.

Traub et al. (1991) therefore constructed a model where the basilar and apical dendrites are each represented by an equivalent cylinder and, together with the soma, comprise 19 compartments. They included six voltage-gated channel types (sodium, calcium, delayed rectifier potassium, A-type potassium, long-duration Ca-dependent potassium, and short-duration calcium- and voltage-dependent potassium (K-C)) and attempted to constrain model kinetics with experimental data as best as possible. Thus, for the first five channel types, model kinetics were taken from voltage-clamp data from isolated hippocampal pyramidal cells. Due to the availability of data, many of the recordings were from CA1 pyramidal cells from guinea pig (e.g., Kay and Wong 1987; Sah et al. 1988; Numann et al. 1987). Although K-C channels were known to exist in CA1 pyramidal cells (Numann et al. 1987), their kinetics were unclear, and thus model kinetics were based on recordings from bullfrog sympathetic neurons (Adams et al. 1982). For network model simulations (consisting of 100 pyramidal cell models), they included a fast excitatory synapse model in two compartments and a slow voltage-dependent synapse (representing an NMDA receptor) in one compartment. Once the kinetics of the channels were defined, they decided upon distributions of peak conductance values that reproduced a

number of current-clamp recordings. Using these fixed parameters, they analyzed how each voltage-gated channel type contributed to the cell model's firing patterns.

The model successfully reproduced a number of electrical properties that are characteristic of CA3 pyramidal cells, such as its ability to generate large dendritic calcium spikes. When somatic depolarizing currents were applied and gradually increased, the model also reproduced the transition from low frequency bursting to high-frequency repetitive firing that is seen in pyramidal cells *in vitro* (Wong and Prince 1981). The network model produced synchronized bursts, although the shape of the bursts was not completely as desired. The model also produced a number of predictions, including that NMDA blockers should suppress secondary (but not primary) bursts and that a novel firing pattern may exist during tonic depolarizing dendritic stimulation.

Pinsky and Rinzel (1994): Firing Patterns in a Reduced Model

Although Traub et al.'s (1991) model (referred to here as Traub's model) reproduced many complex firing patterns of a CA3 pyramidal neuron, the precise biophysical mechanisms required to produce this behavior remained unclear. One can parse out the key mechanisms of a system by creating a minimal mathematical description that accounts for its essential characteristics. With this in mind, Pinsky and Rinzel (1994) created a two-compartment model as a reduction of Traub's 19-compartment model of a CA3 pyramidal cell. Such a minimal model allowed them computational freedom to perform a thorough analysis of the effect of the electrotonic coupling parameters on spiking behavior. They used their model to create a network model and compared the key firing properties of their single-cell and network model with those of Traub et al. (1991).

To construct the two-compartment model, Pinsky and Rinzel noted that the fast-spiking currents, sodium (Na) and delayed rectifier potassium (K-DR), in Traub's model were restricted to the soma and proximal dendritic compartments, whereas the majority of the calcium currents

were in the distal dendritic compartments. Thus, Pinsky and Rinzel created a "soma-like" compartment containing the fast-spiking currents (Na and K-DR) and a "dendrite-like" compartment containing excitatory synaptic currents, the calcium (Ca) current, the calcium-activated potassium current (K-C), and the potassium afterhyperpolarization current (K-AHP). They used the same voltage-gated current kinetics as in Traub et al. (1991). Electrotonic coupling was described by two parameters: one that represented the coupling strength and one that represented the percentage of total area in the "soma-like" compartment (see Fig. 3).

Pinsky and Rinzel found that their simple two-compartment model reproduced several of the major stimulus-response features of Traub's

Hippocampus, Model Excitatory Cells, Fig. 3 A schematic of Pinsky and Rinzel's (1994) two-compartment model of a CA3 pyramidal cell. The soma-like compartment has a sodium (I_{Na}) and potassium delayed rectifier (I_{K-DR}) currents, whereas the dendrite-like compartment contains the calcium (I_{Ca}), calcium-activated potassium (I_{K-C}), potassium afterhyperpolarization (I_{K-AHP}), and synaptic (I_{Syn}) currents. Each compartment also receives an applied current (I_s and I_d for somatic and dendritic compartments, respectively). The coupling strength of the two compartments is given by g_c , where A_{tot} is the total cell membrane area, and p is the proportion of cell area taken up by the soma. The membrane potentials of the somatic and dendritic compartments are represented by V_s and V_D , respectively. (With kind permission from Springer Science+Business Media: *J Comput Neurosci*, "Intrinsic and network rhythmogenesis in a reduced Traub model for CA3 neurons," vol 1, 1994, p. 39–60, P.F. Pinsky and J. Rinzel, Fig. 1A)

model, such as the generation of bursts for weak steady depolarizing current drive to the soma and repetitive single action potentials for a larger drive. They found that steady dendritic stimulation could produce higher frequency bursting than steady somatic input and that bursting only occurred when the coupling strength was within an intermediate range. Bursting depended on having the lower threshold fast currents (Na, K-DR) in electrically separate compartments from the higher threshold slow currents (Ca, K-C, K-AHP), and thus bursting could not occur when they were too strongly or weakly coupled. Similar to Traub et al.'s (1991) network model, Pinsky and Rinzel's network simulations produced synchronized bursting through the stimulation of a single cell. Interestingly, they found that the network quickly desynchronized when the fast excitatory synapses were blocked, even when the network was homogeneous, due to intrinsically chaotic burst dynamics.

Due to the fact that this model captures many complex firing features of CA3 pyramidal cells and is computationally efficient, a number of studies have incorporated this model into their work (e.g., Huang et al. 2007; Taxidis et al. 2012).

DG Granule Cell Models

Dentate gyrus granule cells have properties that make them quite unique from CA1 and CA3 pyramidal cells. Notably, they are not pyramidal in morphology: they have a small cell body with a single conical dendritic tree (Fig. 2c). Unlike pyramidal cells, under healthy conditions, DG granule cells do not form recurrent connections (Claiborne et al. 1986). They are densely packed in the stratum granulosum and therefore outnumber CA1 or CA3 pyramidal cells (West et al. 1991). However, due to their more hyperpolarized resting membrane potential (Penttonen et al. 1997; Spruston and Johnston 1992; Staley et al. 1992), they have low spontaneous rates of firing under most conditions (Penttonen et al. 1997). Thus, recordings of DG granule cell firing patterns can be difficult to obtain *in vivo*. In addition, DG granule cell dendrites are small in diameter,

making them hard to record and therefore limiting the number of studies of dendritic action potential propagation. Thus, there are many questions left to be addressed by experiments and modeling.

Computational models have attempted to further our general understanding of DG granule cell functioning. For example, Vetter et al. (2001) used computational modeling to examine the effects of DG granule cell morphology on action potential propagation. Yuen and Durand (1991) used ion channel properties from other neuron types in their DG granule cell model and investigated what modifications in these channel properties were necessary to reproduce experimentally determined firing patterns. Also, Rusakov et al. (1996) created a DG granule cell model to investigate how spine changes would affect synaptic efficacy, and Ferrante et al. (2009) described how feed-forward inhibition may help shape the neuronal input/output relationship.

Although DG granule cells do not synapse onto each other under healthy conditions (Claiborne et al. 1986), recurrent excitatory circuits have been shown to emerge in epileptic rats (Lynch and Sutula 2000). Here, we describe in more detail a network model that attempts to understand the effect of DG granule cell axonal sprouting and network connectivity on network activity. This model contains four different cell types: DG granule cells, hilar mossy cells, inhibitory basket cell interneurons, and hilar perforant path-associated (HIPP) interneurons. Although the hilar mossy cells are excitatory hippocampal cells, much less experimental work has been done to characterize these cells than on CA1 and CA3 pyramidal and on DG granule cells. Because of this, few models of these mossy cells exist, and details with which to constrain the models are relatively minimal. Thus, we will focus our attention on the DG granule cell model of this DG network model.

Santhakumar et al. (2005): The Effects of Axonal Sprouting on Network Dynamics

The axons of DG granule cells, denoted "mossy fibers", have been shown to sprout due to persistent seizures and head trauma (Golarai et al. 2001; Santhakumar et al. 2001). This sprouting is associated with hyperexcitability of the DG, although

the precise mechanisms of this increased activity are unknown. In particular, it is unclear whether a small amount of sprouting, as is seen in experiments (Santhakumar et al. 2001), can lead to seizure activity. Therefore, Santhakumar et al. (2005) created a computational network model containing DG granule cells to investigate how mossy fiber sprouting (as well as mossy cell death) contributes to network activity (Santhakumar et al. 2005).

Santhakumar et al. (2005) created network models of the DG, based on a 2000:1 scaling down of four major cell types in the DG. The DG granule cell model was adapted from a previously constructed model by Aradi and Holmes (1999) and consisted of nine compartments and a number of voltage-gated channels (sodium; fast and slow delayed rectifier potassium; A-type potassium; L-, N-, and T-type calcium; calcium-dependent potassium; and calcium- and voltage-dependent potassium). As DG hyperexcitability is known to remain in the presence of NMDA blockers (Santhakumar et al. 2000), only AMPA and GABA_A synapses were included. The authors carefully chose their network sizes and network convergences and divergences in accordance with available experimental quantities and considered both topological (incorporating the axonal distribution of cell types) and non-topological (postsynaptic targets were selected at random) networks. Mossy fiber sprouting was modeled through the addition of connections from DG granule cells to DG granule cell proximal dendrites.

Simulations indicated that in the topological networks, even a low degree of mossy fiber sprouting was sufficient to induce seizure-like activity in the DG in response to perforant path stimulation. The spatially restricted axonal distribution of the sprouted mossy fibers played a pivotal part in determining the spread of network activity during seizures in the DG.

Concluding Statement

It is clear that many experimental details of hippocampal excitatory cells exist and that many

specific questions about these cells have been addressed with models. However, further aspects, such as cellular, biochemical mechanisms (e.g., Kim et al. 2010), can also be considered. Furthermore, mathematical models are always simplifications of the biology, and so, when constructing models, it is important to be aware of and to be clear about the constraints and assumptions made. These details and rationales become especially important when creating subsequent models by expanding or reducing previously constructed models. In this way, linkages between experiment and modeling can remain clear, and cycling between the two becomes feasible.

Definition

Hippocampus, model inhibitory cells refer to mathematical models of neurons that are designed to represent (GABAergic) inhibitory interneurons in the hippocampus. Specifically, biophysically motivated models of interneurons located in the CA1, CA3, and dentate gyrus (DG) regions of the

hippocampus are described. These cellular models have been developed for two main purposes: (i) to examine how their biophysical characteristics affect and control electrophysiological output and (ii) to examine network output given the modeled cellular characteristics. This entry summarizes a comprehensive set of such models.

Detailed Description

Introduction and Background Context

The brain consists of two classes of neurons, excitatory and inhibitory cells. Excitatory cells were typically thought to be long ranging with their connections, whereas inhibitory cells were viewed as “local circuit neurons” or interneurons (Shepherd 2003). Today, it is clear that this is not necessarily the case, as some inhibitory cell types have long extensions (e.g., see Jinno et al. 2007). Regardless, the “interneuron” terminology is often used synonymously with “inhibitory cell.”

Inhibitory cells or interneurons in the mammalian brain are also termed GABAergic since their primary neurotransmitter is GABA, which causes an inhibitory, hyperpolarizing response in the postsynaptic cells when GABAergic receptors are activated there. It is now known that even though inhibitory cells represent a much smaller percent of neurons, they exhibit a much wider diversity in their characteristics, relative to excitatory cells (e.g., see Freund and Buzsáki 1996; McBain and Fisahn 2001). Interneurons have distinct morphologies located in various cortical layers, have different axonal targets, express different calcium-binding proteins, and exhibit different firing properties. Determining the functionality of this diversity is challenging (e.g., see Freund and Kali 2008; Kepecs and Fishell 2014). In addition, efforts to systematically classify these diverse GABAergic cells are ongoing (Ascoli et al. 2008; DeFelipe et al. 2013).

The hippocampus (Andersen et al. 2006; Ben-Ari and Represa 2009) has been a heavily studied brain structure due to its experimental accessibility with the slice preparation. Moreover, it expresses several rhythmic and population activities that are correlated with normal (e.g., learning

Hippocampus, Model Inhibitory Cells, Fig. 1 Schematic illustrating two main classes of interneuron types in hippocampus CA1, based on their post-synaptic targets. Also schematized are the layers (I-m., rad., pyr., ori.) where the cell bodies are found and where their targets go, as well as input coming from other regions (perforant path *PP*, Schaffer collaterals (*Sch*)). The first class (shown on the *left*) are interneurons that target perisomatic regions of the excitatory, pyramidal cell. They include basket cells (*BC*, targets: soma and proximal dendrites) and axo-axonic cells (*AA*, targets: axon initial

segments). The second class (shown on the *right*) are interneurons that target dendritic regions. They include bistratified cells (*BS*) that innervate the mid-distal dendrites, neurogliaform (*NG*) interneurons that target apical dendrites, and O-LM interneurons that target the distal apical dendrites (I-m. layer). (With kind permission from Springer Science+Business Media: *Hippocampal Microcircuits* (Cutsuridis, V., Graham, B., Cobb, S. & Vida, I., eds.), Part I, Chapter 2, 2010, p.27–67, I. Vida, “Morphology of Hippocampal Neurons,” Figure 4)

H

and memory) and pathological states (e.g., epilepsy, Alzheimer’s) and in which interneurons appear to have critical, controlling roles (e.g., see Krook-Magnuson et al. 2013). Figures 1 and 2 illustrate several types of interneurons in the hippocampus, either from a dendritic- versus perisomatic-targeting perspective (Fig. 1) or from an interneuron-targeting perspective (Fig. 2). Much work continues to uncover the richness of interneuron diversity (e.g., see Chamberland and Topolnik 2012), and it is clear that we still have much to learn to be able to appreciate and thus understand the functionality of this interneuron diversity.

Mathematical and computational modeling is an essential tool in neuroscience today, and there are many types of mathematical models of neurons ranging from abstract to detailed (Brunel and Hakim 2009). The rationale behind the choices one makes in using a certain type of model naturally depends on the question being addressed. Since the hippocampus expresses several different rhythmic activities, the research questions that are typically considered, in which mathematical

models of hippocampal interneurons are used, either directly or indirectly involve the generation and/or modulation of rhythmic, population activities. Furthermore, it is clear that interneurons play distinct and particular roles in rhythmic activities such as theta and gamma rhythms (► “Hippocampus, Theta, Gamma, and Cross-Frequency Coupling”; ► “Hippocampal Theta, Gamma, and Theta/Gamma Network Models”) (e.g., Klausberger and Somogyi 2008) making them an important focus in modeling studies.

Cellular Models

The amount of detail in a cellular model needs to be enough to allow speculations, hypotheses, and predictions to emerge for future experiments. Interneuron models are either primarily concerned with how inhibitory cells contribute to network rhythms/population oscillations or with characteristics of the individual cells that affect the networks in which they reside. As such, the models tend to be multi-compartment in nature and more detailed for the latter, but not exclusively. Clearly, the more detail that is included in individual cell

Hippocampus, Model Inhibitory Cells, Fig. 2 (continued)

models, the more likely one can adequately represent the characteristics of particular interneurons. However, more detail requires more equations and more parameters which require experimental constraints. In this entry, we tabulate cellular models that have been developed to represent interneurons in CA1, CA3, and DG regions of the hippocampus. Given the cellular, identifiable focus we take, the models are necessarily biophysical in nature, but not always entirely. In particular, the fast-spiking model developed by Ferguson et al. (2013) does not specifically include voltage-gated channels (VGCs), but it does capture spiking characteristics taken directly from experiment. We note that much simpler, cellular representations are used in some studies to allow large networks to be examined along with detailed mathematical analyses (e.g., see Brunel and Hansel 2006; Ledoux and Brunel 2011). The use of identifiable, inhibitory cell-type models is not a focus in such studies.

An anatomically distinct characteristic of hippocampal interneurons, which is likely to be functionally relevant, is the layer-specific targeting of its axons. Specifically, some interneurons preferentially target somatic regions of pyramidal cells, and others target dendritic regions (see Fig. 1). Given this, as well as the range of developed models that exist, we group the models into three tables. Table 1 encompasses models of fast-spiking, basket cell-type interneurons that target perisomatic regions of pyramidal cells. For example, this table includes parvalbumin-positive (PV+) basket cells. We also note that earlier models of hippocampal inhibitory cells are included in this table, as they were developed to be fast spiking (relative to pyramidal cell firing). Indeed, experimental studies often differentiate excitatory and

inhibitory cells based on whether they are fast spiking or not. However, it is now clear that several inhibitory cell types (e.g., Ivy cells – Fuentealba et al. 2008) are not fast spiking. Table 2 encompasses models of interneurons with horizontal dendrites so that their cell bodies and dendrites are in the same layer. These cells target more distal regions of the pyramidal trees. Most of the models in this table are the distal dendrite-targeting oriens–lacunosum-moleculare (O–LM) cells. Table 3 encompasses models of other interneuron types.

For each model in each of the three tables, we identify five aspects:

- (i) The biological interneuron type that the model represents. In some cases, the type is implied.
- (ii) The mathematical model type, identified in three possible ways.
Simple, such that particular biophysical details are not present.
Biophysical and whether *single-* or *multi-compartment* model. The current types (see Glossary) that are included in the model are specified.
Derivative, which could mean *subsequent* use of a given model in another study, typically a network situation, *simplification* of a given model, *adaptation* of a given model, or *expansion* of a given model. The identification of this *derivative* type is meant to be particular and not loose such as when various aspects of various models are used.
- (iii) The experimental basis, considered in three ways. We note that experimental data is obtained from rodents.

^cStated to be applicable to CA1
^dOther derivative model references can be found in Morgan and Soltesz (2010)
^ePassive model characteristics from Nörenberg et al. (2010)

H

Passive properties, considered to be *generic* or *specific* in terms of the particular biological cell type being represented.

Active properties or VGCs (current types), considered to be *generic* or *specific* in terms of the particular biological cell type. *Specific* is used if at least one of the current types is based on data specific to the biological cell type.

Frequency response to injected current or current clamp responses, i.e., *f-I* output curve, considered as *yes* or *no*. *Yes* is specified if the *f-I* curve is shown or if at least two examples of model firing are shown so that it can be seen how firing changes with different levels of injected current. This aspect is chosen because the steepness of *f-I* curves is an important factor to consider in the control of network dynamic output. However, note that all models show firing output that matches experiment in some way.

(iv) Functional aspect considered with the model.

Intrinsic – means that the inhibitory cell model was used to examine how its biophysical characteristics affect and control electrophysiological output (with summarizing specifics given).

Network – means that the particular inhibitory cell model was used when examining

network output (with summarizing specifics given). Also, note that the model network may include other inhibitory cell types as well as excitatory cells with the given inhibitory cell model.

(v) Reference where the given model is described.

Given that we focus this entry on models of identifiable hippocampal interneuron types (as described above), the models given in the tables are a reasonably comprehensive listing. However, we have not included models where only passive properties were considered and only a selection of *derivative* model types is given. We present the models in the tables in a chronological order (of paper publication) with the exception that *derivative* models are presented immediately following the given model and are shown as a shaded entry as well as being starred (*) to highlight that it is a derivative model and not presented in chronological order in the tables.

Considerations

As tabulated above, it is clear that many different models of hippocampal interneurons have been developed, although new “types” of interneurons are still being defined so that models would not yet exist. All biological cell types modeled, except for the non-PV+ Ivy cells, can be found in the schematics of Figs. 1 and 2. We note that although the majority of models include biophysical VGCs,

^bSee Table 1 for derivative model articles

the majority of them do not have an experimental basis that is specifically tied to the biological cell type. Also, more detailed, multi-compartment, biophysical models are not necessarily more specific. While the reasons for this could be multiple, it is often the case that modelers do not have direct access to experimental data, which is probably due to insufficient interactions between modelers and experimentalists. However, a main reason is due to the active and “fluid” interneuron

field, making it challenging to be clear about experimental data and particular cell types. Coupled with the technical limitations of acquiring data from particular cell types, one cannot expect to have experimental constraints for all model aspects. This is in contrast to hippocampal, excitatory cell models where much more experimental data is available, and specific questions have been considered (in this entry ► “Hippocampus, Model Excitatory Cells”).

		f-I – yes		

^aReferred to as CA1^bThis entry also included a MS non-cholinergic model, and derivative models of it representing hippocampal interneurons are in Hajós et al. (2004) and Orbán et al. (2006)^cThe LM/RAD acronym was used by the authors for this interneuron type, but likely part of SCA interneuron types (see Vida 2010)

For inhibitory cell models in the hippocampus, it is essential that the experimental and biological basis be specified, so that future models can more fully take advantage of existing ones. While this should be the case for any model, it is even more so for these diverse, inhibitory cell populations, which are developmentally regulated (see Tricoire et al. 2011), and where diversity and function are probably linked (see Leão et al. 2012).

Glossary

Biophysical: Types of Currents as Given in “Mathematical Model Type”

Ca-L	L-type calcium. Also referred to as high threshold type, non-inactivating
Ca-N	N-type calcium
Ca-T	T-type calcium. Also referred to as low threshold type, inactivating, and associated with post-inhibitory rebound
h-sag	Hyperpolarization-activated (sag) inward
K-A	A-type, transient potassium
K-AHP	AHP potassium. Only calcium dependent, not voltage dependent, apamin sensitive, sometimes referred to as SK, and responsible for slow AHP, but could also be part of medium AHP
K-Ca	Calcium-dependent potassium. Calcium and voltage dependent, sometimes referred to as BK and responsible for fast AHP aspects
K-D	Slowly inactivating potassium
K-DR	Delayed rectifier potassium. HH type

K-DRf	Fast delayed rectifier
K-DRs	Slow delayed rectifier
K-M	Muscarinic, potassium
Na	Sodium. Transient, HH type
Na-p	Persistent sodium

Other Acronyms Used

AAC	Axo-axonic cell
AHP	Afterhyperpolarization
BSC	Bistratified cell
CB+	Calbindin positive
CCK+	Cholecystokinin positive
DG	Dentate gyrus
EPSP	Excitatory postsynaptic potential
GABA	γ -aminobutyric acid
GJ	Gap junction
HH	Hodgkin–Huxley
HIPP	Hilar perforant path associated
IS3	Interneuron-specific-III
LM/RAD	Lacunosum-moleculare/radiatum
MPO	Membrane potential oscillation
MS	Medial septum
N/A	Not applicable
NGL	Neurogliaform
O/A	Oriens/alveus
O-LM	Oriens–lacunosum/pyramidale
PV+	Parvalbumin positive
SCA	Schaffer collateral associated
SOM+	Somatostatin positive
SP	Stratum pyramidale
VGC	Voltage-gated channel

Hippocampus, Model Network Architecture

Sarah Feldt Muldoon

Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, USA

Definition

Hippocampus, Model Network Architecture refers to the mathematical models used to describe cell connectivity and activity in computational models of the hippocampus. Models of the hippocampus contain two main components: (1) the structure of connections between the cells/regions and (2) the cell types used as the building blocks of the model.

Detailed Description

Basic Hippocampal Anatomy

The hippocampus proper is composed of three subregions: CA1, CA2, and CA3. However, many models actually represent the hippocampal formation, which additionally includes the dentate gyrus (DG), subiculum (SUB), presubiculum, parasubiculum, and entorhinal cortex (EC) (Amaral and Lavenex 2006). Many hippocampal models focus on the representation of a single subregion or the interactions between regions. One aspect of the hippocampus that differentiates it from other cortical regions is that connections between subregions tend to be unidirectional, creating loops of which have important implications for information processing. This is especially important given that the hippocampus is involved in functions such as memory, learning, and spatial navigation. Because much of the available experimental data regarding hippocampal structure comes from studies of mice and rats, most computational models are based on what is known about the structure of the rodent hippocampal formation.

Anatomical Structure/Connectivity

The basic connectivity of the hippocampus is generally simplified to represent the following interactions between subregions. The hippocampus receives input from the cortex to the EC. The EC projects to the DG, CA3, CA1, and the SUB through the perforant pathway. The DG sends mossy fibers to CA3, and CA3 in turn projects to CA1. CA1 then projects to the SUB as well as back to the EC, and the SUB also projects back to the EC. The exact nature of these connections can further be deconstructed, and other less prominent connections also exist. Please refer to the “Further Reading” section for references describing the connectivity in more detail.

Cell Types

The hippocampus is composed of excitatory principal cells, inhibitory interneurons, and glial cells. Many models include excitatory and inhibitory cells, but often exclude the contribution of glial cells. However, as recent experimental data

emphasizes the importance of glial-neuronal interactions (Volterra and Meldolesi 2005), more computational models are attempting to include these cells, especially in models of disease such as epilepsy (Volman et al. 2012).

The most studied principal cells of the hippocampus include the pyramidal cells of CA1 and CA3 and the granule and mossy cells of the DG, and detailed biophysical models of these cells have been developed (Vida 2010).

There is a vast diversity of interneurons in the hippocampus (Freund and Buzsaki 1996; Kullmann 2011), and new experimental techniques continue to lead to the classification of new subtypes of these GABAergic cells. Interneurons are normally classified based on their morphology, neurochemical markers, and electrophysiological properties (Ascoli et al. 2008). However, recently, a new class of “hub cells” was functionally identified and could be identified as early-born neurons suggesting that birth date/location of cells might also be important in the classification of interneurons (Bonifazi et al. 2009; Picardo et al. 2011). Biophysical models of the hippocampus often attempt to include interneurons, and detailed models of some subtypes such as basket cells and OLM neurons have been developed (Skinner and Saraga 2010a), but due to the current lack of experimental knowledge about this class of cells, it is difficult to include detailed models of all of the relevant cell types.

While some computational models are based on detailed representations of the cell types found in the hippocampus, many models choose to instead use simplified representations of cells and implement neurons as simply excitatory or inhibitory. For more information, see the “Further Reading” Section.

Types of Models

Because hippocampus is highly organized and complex structure, the first decision that must be made in defining a computational model of the hippocampus is the level of detail that one would like to include. As in all computational models, this will be dependent on the type of questions that

the model is intended to address and the computational power available. The goal of all hippocampal models is to aid in our understanding of hippocampal functioning. Because the hippocampus has been implicated in a wide variety of tasks and diseases, different models choose different levels of abstraction in order to elucidate potential mechanisms that give rise to observed behaviors. One way of classifying hippocampal models is by the level of abstraction used to model cells. In this case, models can roughly be divided into three categories: biophysical models, spiking neuron models, and firing rate models.

Biophysical Models

Biophysical models are composed of cell types whose dynamics are normally derived from Hodgkin-Huxley-type equations. These models can include multiple compartments and sometimes are based off of detailed cell morphology.

A highly detailed biophysical model of the DG was developed (Santhakumar et al. 2005; Dyhrfjeld-Johnsen et al. 2007) and expanded to include over one million cells (Schneider et al. 2012). This model can be implemented in reasonable time using parallel processing and has been used to study the effects of structural network changes associated with epilepsy. In CA1, Olypher et al. simulated a 1 mm patch to study input–output transformations (Olypher et al. 2012), and Cutsuridis et al. implemented a microcircuit model of CA1 to study memory storage and consolidation (Cutsuridis et al. 2010). Ibarz et al. looked at how populations of pyramidal cells can contribute to high-frequency oscillations (Ibarz et al. 2010), while Baker and Olds used realistic spike train stimulations of a highly detailed CA3 pyramidal cell to study phase precession of place cells (Baker and Olds 2007).

The variation in scale of each of these studies demonstrates the different approaches taken in using computational modeling to study hippocampal function. While some strive to include as much detail as possible and take advantage of parallel computing, others prefer to use smaller but still detailed models to tease out the effects of particular parameters. However, in all of these

models, it should be noted that there are still levels of detail that are left out.

Spiking Neuron Models

Instead of implementing biophysical models of neurons, some models prefer to use highly simplified neuronal representations that reflect the oscillatory nature of neurons and often rely on the concept of a threshold value at which the neuron is said to fire an action potential. Perhaps the most well-known spiking neuron model is the leaky integrate-and-fire neuron (Gerstner and Kistler 2002). Because of the simplicity of this type of neuron, models that implement integrate-and-fire neurons can focus on network interactions, heterogeneity, and specific patterns of connectivity without the additional complexity that comes from biophysical neuronal models.

Spiking neuron models have been used to study memory formation (Feldt et al. 2010a), the effects of network structure on the integration of newly generated neurons (Schneider-Mizell et al. 2010), phase precession of place cells (Tsodyks et al. 1996), temporal sequence compression (August and Levy 1999), and interactions between grid and place cells (Jay et al. 2010).

Firing Rate Models

Firing rate models represent a further abstraction of neuronal dynamics and represent cells by their firing rate as a function of time (Dayan and Abbott 2001). These models are often extensions of the Wilson and Cowen model (Destexhe and Sejnowski 2009; Wilson and Cowan 1972) and have been used to explore rephrasing of oscillations in CA3 and the DG (Akam et al. 2012). Firing rate models are often used to study hippocampal memory formation.

Models of Disease

The hippocampus has been implicated in a variety of diseases, and computational models have been employed to study the differences between healthy and pathological network functions. Multiple computational studies have therefore looked

at how changes in hippocampal architecture relate to seizure development in epilepsy (Case and Soltesz 2011; Soltesz and Staley 2008). In temporal lobe epilepsy, cell death and mossy fiber sprouting in the DG have been linked to the development of spontaneous seizures. By incorporating these changes into a previously developed biophysically motivated model of the DG, Morgan and Soltesz used the injured version of the model to predict a role of highly connected hub cells in seizure dynamics (Morgan and Soltesz 2008). Netoff et al. showed that progressively increasing the number of long-range connections in a small-world network model of epilepsy causes the network to transition from normal to seizure and bursting states (Netoff et al. 2004).

Hippocampal atrophy also plays a large role in Alzheimer's disease, and computational models have been used to explore the progression of the disease (Hasselmo 1997) and how changes in hippocampal network architecture can affect memory (Gluck et al. 2006). Additionally, models have explored how alterations in ion channels can lead to observed changes in the theta rhythm of Alzheimer's patients (Zou et al. 2011).

Functional Structure

A main difficulty encountered in developing models of the hippocampus is the lack of knowledge about the exact anatomical connectivity at the level of individual neurons. Often, model neurons are placed in one-dimensional chains or on two-dimensional grids that neglect the unique spatial properties of hippocampal structure. However, an advantage of computational models is that unlike the connectivity of the brain, the exact model connectivity is known, and in both cases, the dynamics of the neurons can be observed. It can therefore be useful to explore a new type of network structure called functional structure or functional connectivity (Feldt et al. 2011).

Functional structure is derived from statistical relationships between neurons. A connection is

said to exist between neuron A and neuron B if they meet some statistical requirement such as synchronous firing. Functional connectivity can sometimes be related to the underlying anatomical connections, although this is not necessarily the case as one can imagine a situation where common inputs to the cells might cause them to fire synchronously even though the two cells are not themselves connected.

By studying the functional connectivity of synchronous network events in the developing hippocampus, the Cossart lab identified the presence of hub (highly connected) neurons that also display a widespread axonal arborization (Bonifazi et al. 2009; Picardo et al. 2011). The Zochowski lab developed the Functional Clustering Algorithm (FCA) that detects groups of synchronously firing neurons and used this to study memory consolidation (Feldt et al. 2009) and the relationship between structure and dynamics in hippocampal cultures (Feldt et al. 2010b). The algorithm was also applied to chronically epileptic networks to show that these networks are composed of spatially clustered synchronous neuronal assemblies (Feldt Muldoon et al. 2013).

Comparison of functional structure derived from model and experimental data can be useful in model validation and help in our understanding of the relationship between neuronal structure and dynamics.

Definition

The hippocampus is a prominent brain structure in the medial temporal lobe known to be important for episodic memory function. Theta (3–12 Hz) and gamma rhythms (25–160 Hz) commonly refer to specific frequency bands of EEG or local field potential (LFP) activity that is generated by neural circuits in the hippocampus during periods of increased neural activity. These neural rhythms function to organize hippocampal spike timing using different temporal scales.

Detailed Description

Brain rhythms play an important role in spike timing and brain communication (Buzsaki 2006; Gray et al. 1989; O'Keefe and Recce 1993). Different brain regions produce distinctly different brain rhythm frequencies that are thought to reflect unique forms of processing important for the localization, parceling, and routing of information within and between regions. Delta (~0.5–2 Hz), theta (3–12 Hz), beta (15–25 Hz), and gamma rhythms (25–160 Hz) have been investigated for decades. It is now known that theta, gamma, as well as the coupling between these rhythms are important for different brain processes such as episodic memory (Axmacher et al. 2010; Belluscio et al. 2012; Canolty et al. 2006; Fuentemilla et al. 2010; Fujisawa and Buzsaki 2011; Lakatos et al. 2005; Tort et al. 2009). Theta and gamma rhythms have been described in both rodent and primates suggesting that brain rhythms and brain rhythm coupling could serve more general brain functions conserved across species.

Theta Rhythms

Theta rhythms (3–12 Hz) arise from the temporal neocortex and hippocampus during active processing of sensory information, during movement, and during rapid eye movement (REM) sleep (Bland and Oddie 2001; Buzsaki 1996; Kramis et al. 1975; Montgomery et al. 2008; Vanderwolf 1969).

How Are They Generated?

Theta rhythms in the hippocampus are generated by a combination of glutamatergic, GABAergic, and cholinergic inputs together with local activity emerging from the spontaneous activity of interneurons and pyramidal cells (Fig. 1) (Bragin et al. 1995; Charpak et al. 1995; Gloveli et al. 2005; Goutagny et al. 2009; Kocsis et al. 1999; Konopacki et al. 1987; Lawson and Bland 1993; Winson 1978). The firing patterns of neurons throughout the brain have been shown to be correlated with hippocampal theta rhythms including those neurons near theta generators in the temporal lobe (Chrobak and Buzsaki 1998; Dickson

Hippocampus, Theta, Gamma, and Cross-Frequency Coupling, Fig. 1

An oversimplified and reductionist model of theta rhythm generation in hippocampal CA1 and subiculum. (a) The minimal circuits required for theta are pyramidal cells and interneurons (Cobb et al. 1995; Goutagny et al. 2009). Activity in CA1 networks will spontaneously give rise to self-generated theta rhythms. The waveform shown above is an example of LFP trace in CA1 without any afferent inputs from the mEC, CA3, or medial septum (MS). (b) The GABAergic inputs from the medial septum are involved in synchronizing these separate intrinsic hippocampal oscillators and therefore creating larger network rhythms. The role of neurons expressing acetylcholine is unclear, although these cells do appear to be crucial for theta generation under urethane anesthesia. The role of glutamate containing MS afferent is currently unknown. Cholinergic and glutamatergic inputs arise throughout the CA1 network, whereas the GABAergic MS inputs are highly

localized to hippocampal interneurons. (c) The afferent excitatory inputs from CA3 and the mEC increase theta power, due to increases in dendritic current influx arising from strong excitatory synapses. These inputs are more likely to have a role in phase modulating the intrinsic rhythms, by slightly advancing (as illustrated) the phase of the rhythms shaped by endogenous- and MS-mediated processes. Phase delays are of course also possible. CA3 and mEC form synapses in different parts of the apical dendrites and therefore can exert their phase and amplitude modifying influence via different mechanisms. The raw data above (b, c) is an example LFP trace taken from CA1 of a freely moving rat. This schematic does not take into account active intrinsic somatic or dendritic conductances to the generation of theta. In addition, numerous subcortical regions modify theta rhythm frequency and amplitude through actions on the MS and local hippocampal circuits. For a review, see Bland and Oddie (2001)

et al. 2000, 2003; Konopacki et al. 1987; Mizuseki et al. 2009) and in connected subcortical regions such as the hypothalamus, amygdala, and striatum (Bland and Oddie 2001; Kirk et al. 1996; Pape et al. 2005; van der Meer and Redish 2011). Therefore, theta frequency activity occurs within brain-wide networks and often the theta

synchronization between regions originates in part from the hippocampus (Battaglia et al. 2011). These data suggest that the hippocampus serves as a central brain hub governing the synchronization of large-scale brain-wide networks at theta frequencies. This is further supported by large-scale brain network topological analysis

that shows that there is a concentration of information flow to the hippocampus (Mišić et al. 2014). The main theta modulating input to the hippocampus arises from the medial septum (MS). The MS sends glutamatergic, GABAergic, and cholinergic inputs to the hippocampus. Cholinergic inputs are not required for theta generation (Lee et al. 1994; Simon et al. 2006) but may contribute to initiation and termination of the theta state (Zhang et al. 2010). GABAergic inputs however have been suggested to play a more prominent role in the fine structure of theta rhythms by making synaptic contacts onto local interneurons in the hippocampus (Freund and Antal 1988), thereby creating a brief period of synchronous disinhibition in hippocampal pyramidal cell networks (Toth et al. 1997). This circuit disinhibition is thought to be responsible for providing the window within which pyramidal cells fire, creating the depolarized phase of the theta wave. Indeed, GABAergic MS lesions do reduce the amplitude of theta; however, with complete MS lesions, small theta rhythmic activity is still found within the hippocampus, and cellular activity still shows signs of theta periodicity (Brandon et al. 2011; Leutgeb and Mizumori 1999). Glutamatergic MS cells form synaptic contacts onto pyramidal cells in the hippocampus and are also likely playing a role in the septal influence on theta rhythms (Huh et al. 2010). One major open question in theta rhythm research is which cell types in the hippocampus are important for local theta generation. Several subclasses of interneurons fire phase locked to hippocampal theta (Klausberger and Somogyi 2008), and different models have ascribed various levels of importance to each interneuron class (► “Hippocampus, Model Inhibitory Cells”). Somatostatin (SOM)-positive interneurons fire at theta bursts (Klausberger et al. 2003) and receive excitatory theta frequency input from the MEC (Witter et al. 1988) as well as cholinergic input from the medial septum. SOM cells may be crucial for amplifying theta-modulated synaptic activity arising in the hippocampus from the medial septum, from the medial entorhinal cortex (MEC), or from the Schaffer collateral circuits of CA3 (Kispersky et al. 2012; Leao et al. 2012).

Theta Rhythms and Behavior

Theta rhythms play a key role in controlling spiking timing in the hippocampus during locomotion, during sensory processing, and during memory tasks (Kramis et al. 1975; O’Keefe and Recce 1993). Specifically, as rodents move through space, hippocampal pyramidal cells fire at an increased rate when moving through the cell’s “place field.” During the place field traversal, the firing rate increases, and cells fire at progressively earlier phases of the hippocampal theta rhythm, a phenomena termed phase precession (Huxter et al. 2003) (Fig. 2). In doing so, place cell spiking provides a phase code which can be used to indicate the animal’s position in the environment based on the theta phase of firing. The mechanism of phase precession is debated, although one theory postulates interference between an oscillatory excitation at apical dendrites and slower inhibitory oscillations acting at the soma via local interneurons (Losonczy et al. 2010; O’Keefe and Burgess 2005). However, the network mechanisms of precession are not definitively known, and there is debate regarding if precession is generated by synaptic inputs to the hippocampus or from local dynamics within hippocampal circuits (Mizuseki et al. 2009).

Grid cells in the MEC are also theta modulated and fire at theta frequencies with phase modulation to the local theta rhythm (Stensola et al. 2012). Theta rhythm communication is thought to be fundamental for communication between these different regions of the hippocampus during episodic memory processes such as spatial navigation in rodents (Buzsaki and Moser 2013).

Gamma Rhythms

Gamma frequency activity (25–160 Hz) refers to bursts of fast frequency rhythms found in spiking, LFP, EEG, and electrocorticography (ECoG) forms of time series data. The specific bandwidths change depending on the preparation, species, experimental conditions, and brain region, and likely different gamma rhythms arise from distinct circuit mechanisms. Two main frequency bands have been described and referred to as slow (~25–50 Hz) and fast (~65–140 Hz) gamma. Different brain regions often preferentially generate

Hippocampus, Theta, Gamma, and Cross-Frequency Coupling, Fig. 2 Phase precession of a hippocampal pyramidal cell on a linear track. (a) Schematic showing the path taken during the run from *left* to *right* on a representative trial. (b) The firing rate heat map showing the location versus firing rate, with the obvious location of the cell's place field. Warmer colors code for higher firing rate. (c) The relationship between the theta waves (LFP,

black) and place cell spiking (spike times indicated in *red*). Note precession of the spike relative to the theta cycle, where the spike fires at progressively earlier theta phases as the rat moves through the place field. The ticks above are the zero-crossing times of the individual theta cycles (180°). The vertical lines indicate 270° within the theta cycle (Data are reproduced from Huxter et al. (2003) with permission)

one of the two frequencies, although shifts between gamma frequencies can serve to change the communication between different regions on a rapid time scale gamma (Buzsaki and Wang 2012).

How Are They Generated?

Two main models of gamma rhythms are proposed to account for the physiological mechanisms of gamma synchrony in the brain (Buzsaki and Wang 2012) (► "Hippocampal Oscillations, Mechanisms (PING, ING, Sparse)"). The first model, PING, requires balanced excitation and inhibition between pyramidal cells and interneurons (Csicsvari et al. 2003; Fisahn et al. 1998). In this model, excitatory pyramidal cells provide feed-forward excitation of interneurons, which then provide inhibitory feedback to the comparatively more numerous pyramidal cell population. The pyramidal cells recover from inhibition synchronously, and thus their post-inhibitory rebound spiking starts the subsequent gamma cycle by depolarizing interneurons. The second model, ING, postulates inhibitory interactions between

interneurons which can sustain gamma frequency synchronization (Buzsaki and Wang 2012; Whittington et al. 1995) via tonic depolarization of connected interneurons. No single model of gamma rhythm likely captures the heterogeneous mechanisms by which different gamma frequencies are generated. However, support for both models has been provided by different experimental data sets (Buzsaki and Wang 2012). The cell type most often associated with gamma rhythms is the parvalbumin (PV)-positive basket cell (Gulyas et al. 2010). These basket cells fire in vivo with bursts of activity at high frequencies and provide somatic inhibition to local pyramidal cells as well as other PV-positive cells. Inhibition of PV cells in the neocortex reduces local gamma rhythms (Sohal et al. 2009). However, an analysis of gamma rhythms in the hippocampus following PV cell suppression has not been reported.

Roles and Characteristics

The different frequencies (slow and fast) of gamma may arise from different network mechanisms (Bragin et al. 1995; Colgin et al. 2009) or

from different parameter regimes of the same synaptic components (Mann and Mody 2010). Different gamma frequencies can be present during different behavioral states (Ahmed and Mehta 2012; Colgin et al. 2009) and could thus serve to assist in signaling information between specific pathways. In the context of the hippocampus, gamma rhythms can be generated by intrinsic hippocampal circuits in CA3 (Bragin et al. 1995; Fisahn et al. 1998) and the subiculum (Colling et al. 1998; Jackson et al. 2011; Stanford et al. 1998) in addition to cortical regions that communicate with hippocampal circuits, including the medial entorhinal cortex (MEC) (Charpak et al. 1995; Colgin et al. 2009; Quilichini et al. 2010). Therefore, the cortex and hippocampus are wired to communicate using these gamma frequencies presumably through the phase coupling of independent gamma oscillators. Gamma frequency coherence between hippocampal regions is high during working memory tasks (Montgomery and Buzsaki 2007), suggesting gamma coherence serves to link together regions in a task-dependent manner. However, gamma rhythms *in vivo* are generally not persistent (unlike in brain slice preparations) and occur in brief bursts which are “theta modulated”; thus the amplitude of gamma follows the phase trajectory of theta rhythms (Fig. 3). This property of theta-modulated gamma is known as cross-frequency coupling or, specifically in this instance, theta–gamma coupling and provides a mechanism to simultaneously process multiple frequencies of network activity being relayed between brain areas. Further roles are described below.

Theta–Gamma Coupling

Theta–gamma coupling can be grouped into two forms: (1) phase–amplitude coupling, which refers to the phenomenon where the phase of the theta rhythm modulates the amplitude of the gamma frequency (Fig. 3), and (2) phase–phase coupling, where the phases of gamma and theta covary due to gamma waves occurring at preferred phases of theta (Belluscio et al. 2012). These forms of rhythm coordination are just two examples of cross-frequency coordination found in the brain. Theoretically, many other types of

coupling could exist (► “[Theta-Gamma Cross-Frequency Analyses \(Hippocampus\)](#)”).

The observation of covariation between theta phase and gamma amplitude was first quantified by Bragin and colleagues who described theta–gamma coupling in rat CA1 using LFP and single neuron recordings (Bragin et al. 1995). This original observation was not intensively followed up until Canolty and associates showed that ECoG recordings in humans demonstrated robust theta–gamma coupling and the strength of this coupling correlated with behavioral performance on memory tasks (Canolty et al. 2006). Since these reports, this interesting form of frequency multiplexing has been the subject of intense study by many experimental and theoretical neuroscientists (Axmacher et al. 2010; Belluscio et al. 2012; Canolty et al. 2006; Canolty and Knight 2010; Colgin et al. 2009; Pastoll et al. 2013; Sauseng et al. 2010; Sirota et al. 2008; Tort et al. 2009; Wulff et al. 2009). Although relatively few studies have focused on the mechanisms of theta–gamma coupling, many studies have described this phenomenon in different brain regions, in different species, and under different laboratory settings. This suggests that this cross-frequency coordination is a general property of oscillatory neural circuits and that optimal circuit function produces nonlinear coupling between different frequencies of neural activity (He et al. 2010). However, neural data analyses must be carefully done and considered in extracting cross-frequency properties (Aru et al. 2015; Hyafil 2015, 2017; Lozano-Soldevilla 2018). Bringing mechanistic and functional understanding together is clearly needed (Hyafil et al. 2015), and various modeling studies exist (► “[Hippocampus, Model Excitatory Cells](#)”; ► “[Hippocampus, Model Inhibitory Cells](#)”; ► “[Hippocampal Theta, Gamma, and Theta/Gamma Network Models](#)”).

Role in Behavior

One function of theta–gamma coupling was proposed in working memory (Lisman and Idiart 1995). During working memory tasks, individuals must maintain several items (words, digits, letters, etc.) in working memory in preparation for subsequent recall. It was proposed that the number of

Hippocampus, Theta, Gamma, and Cross-Frequency Coupling, Fig. 3 (a) Spontaneous, theta–gamma (phase–amplitude) coupling in the subiculum of the isolated hippocampus in vitro. The LFP from the deep layer of the subiculum was filtered in the theta band (3–10 Hz) and in the fast gamma band (100–150 Hz). Note that the amplitude of the gamma rhythms is modulated by a theta frequency, and increases in gamma amplitude occur near the theta peaks, demonstrating theta–gamma, phase–amplitude coupling. (b) Five examples of cross-frequency coupling analysis in different preparations (indicated above). The analysis quantifies the degree of phase–amplitude

coupling for all frequency pairs (phase x-axis vs. amplitude y-axis). The warmer colors indicate stronger coupling (modulation index) between the phase and amplitude. Note the prominent region of phase amplitude coupling near 140 Hz in all cases corresponding to the frequency band known as fast gamma, high-frequency oscillations (HFOs), or epsilon (Schomburg et al. 2012). See Tort et al. 2009 or Tort et al. 2010 (Journal of Neurophysiology) for a description of the details underlying the quantification of the phase amplitude coupling (Panel b is reproduced from Tort et al. (2013) with permission)

gamma cycles within the theta cycle set the limit on working memory capacity (roughly four to seven items). According to this theory, recently encoded items are temporarily stored in working memory by theta–gamma coupling where each item corresponds to one gamma cycle and the temporal order of item encoding is preserved by the order of each gamma cycle within the theta cycle. The encoding of more items would require the slowing of the theta cycle in order to accommodate more gamma cycles and more working memory items (Jensen and Lisman 1996). Recent data by Axmacher et al. (2010) have shown that

theta–gamma coupling is correlated with short-term memory; however, the gamma frequency also slows with increased memory load, suggesting each item to be recalled is not represented by a single gamma cycle as proposed by the original hypothesis (Jensen and Lisman 1998; Lisman and Idiart 1995). Other insights into the function of cross-frequency theta–gamma coupling have come from specifically analyzing the large-scale brain-wide dynamics of theta–gamma coupling during different memory tasks in humans (Fuentemilla et al. 2010; Jacobs and Kahana 2009; Mormann et al. 2005; Sauseng

et al. 2009). Collectively, this growing body of work has shown that when items are maintained in working memory, theta–gamma coupling is present, and the strength of theta–gamma coupling predicts the performance on the task. Additionally, the presentation of specific stimulus features during stimulus presentation is accompanied by distinct theta–gamma “signatures” where the spatiotemporal dynamics of theta–gamma is different for separate stimulus features (Jacobs and Kahana 2009).

Work in rodents has shown that in CA3 theta–gamma coupling increases as rats learn to discriminate between different spatial contexts (Tort et al. 2009). In a separate task, Tort et al. trained rats to use an auditory cue to signal the requirement of either a left or right turn on a T-maze (Tort et al. 2008). The authors found specific theta–gamma signatures at distinct spatial locations within the task maze, and that coupling reaches a maximum at the time when the cue was delivered. In addition, the cross-frequency coupling underwent a different time course in the striatum versus the hippocampus. These studies suggest that there are rapid brain-wide theta–gamma coupling changes that accompany specific parts of the task. Furthermore, this work highlights how hippocampal theta could coordinate the changes in gamma activity in other regions through inter-region theta–gamma coupling, demonstrating a more general function of theta–gamma coupling in long-range brain communication. In this regard, a landmark study has shown that hippocampal theta rhythms phase modulated gamma rhythm generators throughout the entire neocortex (Sirota et al. 2008), posing interesting and challenging new questions regarding long-range hippocampal communication through this form of cross-frequency coupling.

How Is Coupling Produced?

The coordination of both theta and gamma rhythms is most likely an emergent phenomena arising from the large-scale integrative properties of separate rhythm-generating neural networks. Gamma rhythms (Atallah and Scanziani 2009; Cunningham et al. 2003; Fisahn et al. 1998) and theta rhythms (Goutagny et al. 2009; Konopacki

et al. 1987) can be generated locally by different intrinsic hippocampal circuits. Therefore, it has been difficult to investigate the mechanisms of how these two distinct frequencies become coordinated. Mechanistically, theta–gamma coupling can be divided into the microcircuit and macrocircuit levels. Macrocircuit coupling assesses the large-scale coupling mechanisms between regions, for example, theta in one region and gamma in another (Quilichini et al. 2010; Sirota et al. 2008). Microcircuit theta–gamma coupling refers to instances where the same groups of neurons are simultaneously participating in generating both rhythms, for example, in local hippocampal or entorhinal networks where both rhythms are generated (Gloveli et al. 2005; Jackson et al. 2011; Montgomery et al. 2008; Pastoll et al. 2013). These two levels are of course not mutually exclusive, but this dichotomy provides a useful starting point for investigation and discussion of the relevant literature.

At the level of the microcircuit, hippocampal theta–gamma coupling requires pyramidal cells and interneurons, as both cell types fire and are simultaneously phase locked to theta and gamma rhythms (Bragin et al. 1995; Csicsvari et al. 1999; Senior et al. 2008). However, different subtypes of interneurons are likely differentially involved (Klausberger et al. 2003; Klausberger and Somogyi 2008; Lapray et al. 2012; Laszotzci et al. 2011). Bistratified and somatic targeting PV-positive interneurons fire phase locked to gamma rhythms (Tukker et al. 2007) while simultaneously firing phase locked to theta. Other interneuron subclasses such as the SOM interneurons phase lock to theta rhythms without phase locking to gamma (Klausberger et al. 2003; Tukker et al. 2007).

The use of optogenetics has provided the ability to causally test the role of cell types in network activity. Using these tools, it was recently shown that theta–gamma coupling in the MEC can arise through feedback inhibition between fast-spiking (FS) interneurons and layer II stellate cells (SCs) (Pastoll et al. 2013). Simultaneous theta frequency depolarization of both cell types resulted in strong excitation of interneurons, which in turn provided inhibitory feedback to produce rapid

gamma frequency IPSCs to SCs and consequently produced theta–gamma coupling both in the extracellular field potentials and in single cell membrane potential activity. Therefore, in this case the MEC theta frequency drives the occurrence and dynamics of gamma activity. In this model, theta–gamma coupling does not require synaptic connections between excitatory neurons. However, theta–gamma coupling was reduced by blockade of glutamatergic synaptic transmission because of the reduced drive onto inhibitory interneurons.

At the macrocircuit level, theta–gamma cross-regional coupling is even less well understood. Although it is well known that theta phase in the hippocampus coordinates gamma frequency activity in the striatum (Tort et al. 2008) and throughout the rostral–caudal neocortical axis (Sirota et al. 2008), very few studies have systematically tried to decipher the anatomical basis of this form of interregional brain coordination. Hippocampal outputs are mainly excitatory; however, recent data has shown long-range inhibitory–inhibitory connections from hippocampus to extra-hippocampal regions (Jinno et al. 2007) as well as GABAergic cells connecting different regions of the hippocampal formation itself (Ceranik et al. 1997; Melzer et al. 2012). It remains to be determined exactly how hippocampal theta rhythms coordinate gamma throughout numerous extra-hippocampal structures, and therefore, future experiments with cell-type-specific inactivation techniques will be required to test the mechanisms of long-range cross-frequency coupling.

Conclusions

Theta and gamma rhythms are the main oscillatory electrophysiological patterns found in the hippocampus and temporal lobe. Different forms of theta and gamma arise in different behavioral states and from different anatomical pathways and synaptic mechanisms. The coordination between frequencies can arise from coupling between theta and gamma rhythm generators, and different regions likely have

different coupling mechanisms which reflect the unique neural architecture of each region. Collectively, the simultaneous generation of these two rhythms shapes the spike timing of nearly all the pyramidal cells and interneurons in the hippocampus. Therefore, these network patterns are of utmost importance for temporal lobe functions such as episodic memory.

Hodgkin-Huxley Model

David Beeman

University of Colorado, Boulder, CO, USA

Synonyms

Action potential model; Squid axon model

Definition

The Hodgkin-Huxley model is a mathematical model of current flow through ion-selective channels in neural membrane. Hodgkin and Huxley were able to describe the time behavior of the

intracellular membrane potential and the currents through potassium (K) and sodium (Na) channels with simple first-order ordinary differential equations. This was done using parameters fitted from their ► **“Voltage Clamp Technique”** measurements on the giant axon of the squid. With this model, they quantitatively described the generation of action potentials by current injection and observable behavior such as the *refractory period* and the *anode break* phenomenon. With other sets of parameters, the Hodgkin-Huxley model has been used to describe many other types of voltage-dependent ion channels and has become a standard technique in *compartmental modeling* of neurons.

Detailed Description

Background

In a series of five classic papers published in 1952, Alan Hodgkin and Andrew Huxley, along with Bernard Katz (Hodgkin et al. 1952; Hodgkin and Huxley 1952a, b, c, d), described the results of experiments on an isolated segment of the giant axon from the squid *Loligo*. For these experiments and the resulting model, Sir Alan Hodgkin and Sir Andrew Huxley were awarded the Nobel Prize in Physiology and Medicine in 1963 (shared with Sir John Eccles for his work on synaptic transmission).

Although these results, and the model that gives them a quantitative description, were concerned with the generation and propagation of action potentials in the squid axon, they form the basis of our understanding of neuronal firing in general. The story of the relationship between experiment, theory, and numerical simulation in these papers exemplifies the way that computational neuroscience combines experimental and theoretical approaches to use simulation as a tool for understanding neural systems.

The squid giant axon is specialized for the rapid conduction of action potentials that are used to trigger contractions in the squid mantle, as an escape reflex. A short piece of the axon with the ends tied off, and immersed in seawater, was the ideal preparation for these pioneering

experiments because the large diameter of 0.5 mm allowed its exploration with the tools of the time and because the variable conductance of its membrane was dominated by just two currents, sodium (Na) and potassium (K), rather than the dozens of ionic current types found in most neurons.

In this *voltage clamp* experiment, two thin silver wires were inserted along the length of the axon for 30 mm. One was used to record the internal membrane potential relative to the exterior solution. The other was connected to a feedback amplifier that measured the difference between the membrane potential and a desired “control voltage” and that injected the proper amount of current through this electrode to maintain the membrane potential at the control voltage. With this arrangement, Hodgkin and Huxley were able to measure the current needed to maintain the membrane potential at any particular level and indirectly calculate the channel conductances.

This was done with a series of voltage clamp experiments that measured both the total current and the current when the Na conductance was disabled. They eliminated the sodium current by replacing the seawater with a solution containing choline instead of sodium chloride. Modern experiments use a puffer fish neurotoxin tetrodotoxin (TTX) to block the sodium channels.

During more than 60 years since the publication of this work, many varieties of sodium-, potassium-, and calcium-selective channels, including calcium concentration-dependent potassium channels, have been discovered and studied in a wide variety of neurons. These occur in the soma and dendrites of the cells as well as the axon and are responsible for the wide variety of observed neuronal firing patterns. With appropriate parameters obtained from voltage clamp experiments, variations of the Hodgkin-Huxley model are used to simulate their behavior in detailed models of neurons.

Basis of the Model

At the time, little was known about the nature of the cell membrane or even the existence of

channels through which ions could pass. It was known that the membrane was semipermeable to ions and that it surrounded a conducting cytoplasm of comparatively low resistance. In effect, it acted like a leaky cylindrical capacitor.

Figure 1 illustrates the conceptual model behind the mathematical model.

It was also known that the concentration of sodium ions is greater outside the axon, so they have a tendency to enter. The concentration of potassium ions is greater on the inside, so they tend to leave. Metabolic processes within the cell called ionic pumps maintain this balance of concentrations.

Because of the difference in ionic concentrations, when the cell is at rest and the axon is not firing action potentials, the interior is polarized to a membrane potential E_{rest} of about 70 mV negative from that outside. This produces an attractive electrostatic force on the positively charged ions, in addition to the diffusive force produced by the concentration gradients.

Due to its higher exterior concentration, Na has a tendency to enter the cell unless the membrane potential is raised to a high enough value so that the electrostatic repulsion of the ions cancels the osmotic force of diffusion. Hodgkin and Huxley (1952a) applied the ► “Nernst Equation” to calculate this *reversal potential* or *equilibrium potential* E_{Na} from the known interior and exterior Na concentrations and found it to be about 45 mV positive with respect to the extracellular potential. Likewise, this competition between osmotic and electrostatic forces means that potassium will tend to leave unless the membrane potential falls below the negative reversal potential E_{K} of about -82 mV relative to the exterior. Most neuroscience textbooks (e.g., Kandel et al. 2000) explain how these equilibrium potentials are calculated from the

Nernst equation and the how the rest potential can be calculated from what has become known as the Goldman-Hodgkin-Katz voltage equation.

At this time, it was only their hypothesis that the interplay of the Na and K currents was responsible for the production of the action potential. From the results of the their experiments, they reasoned (and demonstrated quantitatively with their model) that depolarization of the cell (an increase in membrane potential relative to the outside) causes Na-selective channels to open, allowing Na ions to enter. This raises the potential, further increasing the conduction of the Na channels, and causes the neuron to fire an action potential. Eventually, the Na channels inactivate, and K-selective channels begin to open, causing a flow of charge out of the cell, ending the action potential. This is followed by a period of hyperpolarization to a potential below the resting potential, which is responsible for the “refractory period” during which another stimulus is unable to cause an action potential.

In Part I of the final paper of the series, Hodgkin and Huxley (1952d) reviewed the experimental results from the previous papers. They saw that the observed changes in permeability of the membrane depended on the membrane potential, and not on the current through the membrane. The channels acted in accordance with Ohm’s law, with a current proportional to the voltage drop across a channel conductance. The voltage drop for a particular ionic conductance would be the difference between the membrane potential and the equilibrium potential for that ion. That led to a model based on an electrical circuit similar to the one shown in Fig. 2.

In this figure, V_m represents the membrane potential at a point inside the axon, relative to a point outside the cell in the seawater or other extracellular fluid. The relatively nonconducting cell membrane that separates the conducting cytoplasm from the surrounding solution acts as a membrane capacitance C_m in parallel with the resistors and batteries. The membrane capacitance can be charged or discharged as current flows into or out of the compartment, changing the value of V_m . This current can come from the passage of ions through ion channels or from a current I_{inject}

Hodgkin-Huxley Model, Fig. 1 Ion flow in the Hodgkin-Huxley model

Hodgkin-Huxley Model, Fig. 2 The equivalent electrical circuit of the Hodgkin-Huxley model

through the injection electrode inserted into the axon segment.

The resistor symbols with the arrows through them represent the two variable conductances for Na and K ions. The fixed “leakage conductance” G_L represents conductance of passive channels, primarily selective for chloride ions, that have little or no voltage dependence. By convention, these are represented by a conductance, G , rather than a resistance, $R = 1/G$. Each one of these conductances has an associated equilibrium potential represented by a labeled battery.

In Part II, Hodgkin and Huxley went on to construct the mathematical model corresponding to this circuit.

The Mathematical Model

Electrical circuit theory states that the rate of change of the voltage across the capacitance is proportional to the net current that is applied to charge it, or

$$C_m \frac{dV_m}{dt} + I_{\text{ion}} = I_{\text{inject}} \quad (1)$$

where the ionic current through the three conductances is

$$I_{\text{ion}} = G_{Na}(V_m - E_{Na}) + G_K(V_m - E_K) + G_L(V_m - E_L) \quad (2)$$

These may be combined to give

$$C_m \frac{dV_m}{dt} = G_{Na}(E_{Na} - V_m) + G_K(E_K - V_m) + G_L(E_L - V_m) + I_{\text{inject}} \quad (3)$$

Readers who are familiar with electrical circuit theory may wonder why the ionic current appears on the left-hand side of Eq. 1 and why the arrows labeled with currents in Fig. 2 point from the inside to the outside. Normally, one would expect that currents that enter the cell segment, charging the capacitor to a higher potential, will be considered as positive in sign. This is the case with injection currents and with currents from neighboring segments when the circuit is extended for *compartmental modeling* of neurons. However, Hodgkin and Huxley used what has been called the “physiologists’ convention” in referring to ionic currents as positive when they are outward, not inward. Perhaps this convention arose because the currents being measured were those being provided by the clamp circuitry (I_{inject}) and are equal and opposite to the total ionic current when the voltage is held constant.

Another convention to note is that Hodgkin and Huxley gave all voltage measurements relative to the resting potential of the axon interior. Figure 1 reflects the modern convention of measuring potential differences with respect to the exterior medium. This results in the value $E_{\text{rest}} = -70$ mV and the equilibrium potentials shown in the figure. The Hodgkin-Huxley convention measures these relative to $E_{\text{rest}} = 0$.

Note that Eq. 3 will be the same, no matter which sign convention is used or which value is used as the reference for measurements of potential. Some neural simulators, such as GENESIS (Bower and Beeman 1998, 2003; Cornelis et al. 2012), consider all inward currents, including ionic currents, to be positive. The plots in the simulation examples that are shown in this entry use the Hodgkin-Huxley conventions for current sign and membrane potential.

In order to solve this equation for the time behavior of V_m , given a specified injection current, it was necessary to find equations for the time and voltage behavior of the Na and K conductances, using parameters fitted from the

voltage clamp experiments. This was the most significant aspect of the model. By performing the experiments with different values of the clamp voltage, they were able to determine the time dependence and equilibrium value of the conductances at different voltages.

Figure 3, reproduced from Hodgkin and Huxley (1952d), shows the behavior of the K conductance when the voltage is stepped to 25 mV above the rest potential and then brought back down to the rest potential. For different clamping voltages, they found different values of the maximum conductance and different time behaviors.

It would be tempting to fit the rise of the conductance to an exponential function of time, but the experimental measurements were best fitted by an exponential to the fourth power. They were able to fit the K conductance to an equation of the form

$$G_K = \bar{g}_K n^4 \quad (4)$$

where n is a dimensionless variable with values from 0 to 1, referred to here as the “activation state variable” for K. $\bar{g}_K$ is the scaling factor for K conductance, which Hodgkin and Huxley expressed in units of millimho/cm². The modern unit for conductance is Siemens (the inverse of ohm), so this would be mS/cm².

They postulated that the time behavior of n was given in terms of two voltage-dependent parameters $\alpha_n(V)$ and $\beta_n(V)$ with the differential equation

$$\frac{dn}{dt} = \alpha_n(V)(1 - n) - \beta_n(V)n \quad (5)$$

Under the voltage clamp conditions shown in Fig. 3, this equation has a simple solution, governed by a single time constant τ_n for the value of n as the voltage is stepped upward:

$$n(t) = n_\infty(V) - (n_\infty(V) - n_\infty(0))e^{-t/\tau_n}. \quad (6)$$

Here, $n_\infty(V)$ represents the value of n after a long period of time after a step to voltage V , corresponding to its maximum conductance value shown in the figure. $n_\infty(0)$ corresponds to the steady conductance value at the rest potential before the voltage step. The quantities $n_\infty(V)$ and $\tau_n(V)$ are related to $\alpha_n(V)$ and $\beta_n(V)$ by

$$n_\infty(V) = \alpha_n(V)/(\alpha_n(V) + \beta_n(V)) \quad (7)$$

and

$$\tau_n(V) = 1/(\alpha_n(V) + \beta_n(V)) \quad (8)$$

The injection current is known, the leakage current depends only on the voltage and a constant value of conductance, and the Na current was eliminated. Thus, Hodgkin and Huxley could fit the values of G_L , $\bar{g}_K$, $\alpha_n(V)$ and $\beta_n(V)$ by using different values of the clamp voltage in the absence of Na ions.

Their fit for the Na conductance was a little different, because they found that at a fixed voltage, the conductance rose with time and then decreased exponentially with time, even when the clamping voltage was maintained (Hodgkin and Huxley 1952c). This required a fit to the equation

$$G_{Na} = \bar{g}_K m^3 h \quad (9)$$

Hodgkin-Huxley Model,
Fig. 3 (a) Rise of potassium conductance associated with a depolarization of 25 mV and (b) fall of potassium conductance associated with a repolarization to the resting potential. (Reproduced from Hodgkin and Huxley (1952d), Fig. 2)

Here, m is the activation variable for Na, and h is called the “inactivation state variable,” because it becomes smaller when m (and the membrane potential) becomes larger. m and h obey equations similar to the ones for n but with different voltage dependences for their steady-state values and time constants.

By conducting a similar series of voltage clamp experiments in the presence of Na, Hodgkin and Huxley were able to measure the Na current in isolation by subtracting the currents that were measured without Na. The resulting parameter fits resulted in the equations

$$\alpha_n(V) = \frac{0.01(10 - V)}{\exp\left(\frac{10 - V}{10}\right) - 1} \quad \beta_n(V) = 0.125 \exp(-V/80)$$

$$\alpha_m(V) = \frac{0.1(25 - V)}{\exp\left(\frac{25 - V}{10}\right) - 1} \quad \beta_m(V) = 4 \exp(-V/18)$$

$$\alpha_h(V) = 0.07 \exp(-V/20) \beta_h(V) = \frac{1}{\exp\left(\frac{30 - V}{10}\right) + 1}$$

The model is then fully specified with the following parameters (the reversal potentials are measured relative to the rest potential; see above):

$$C_m = 1.0 \mu\text{F}/\text{cm}^2; E_{Na} = -115 \text{mV}; E_K = +12 \text{mV}; E_L = -10.613 \text{mV}$$

$$\bar{g}_{Na} = 120 \text{ mS}/\text{cm}^2; \bar{g}_K = 36 \text{ mS}/\text{cm}^2; \bar{g}_{leak} = 0.3 \text{ mS}/\text{cm}^2$$

This detailed model of the behavior of the Na and K conductances during a voltage clamp experiment was a remarkable accomplishment. But the outstanding success of the Hodgkin-Huxley model was revealed in the third and final part of the fifth paper (Hodgkin and Huxley 1952d).

Reconstruction of Nerve Behavior

The preceding analysis and parameter fitting were applied to the solution to Eq. 3 for V_m and the coupled equations for conductances under a very unnatural stimulus, the voltage clamp. If this model correctly represents the ionic currents that are responsible for the behavior of the axon, it should be able to predict and help understand the behavior under more natural conditions of greater interest.

In Part III, Hodgkin and Huxley described their numerical solution to the coupled differential equations. The calculations were carried out on “hand-crank” mechanical calculators using a step-by-step iterative process of calculating V_m from Eq. 3 for a step forward in time, calculating new values of the state variables n , m , and h , and repeating. It took weeks to produce the results.

After verifying that their model gave an acceptable fit to the voltage clamp experiments, they went on to correctly calculate the form of the action potentials produced by a depolarizing injection pulse and quantitatively described the *refractory period* during which an axon or cell cannot be stimulated to produce an action potential and the phenomenon of *anode break*.

All of this was done with no changes to the parameters that were used to reproduce the voltage clamp results. This principle of fitting parameters to “function-neutral” experiments that are not directly related to the behavior of interest is an important one in computational neuroscience (Bower 1995). If a computational model produces behaviors that were not used to generate the model, it is possible to have some confidence that the underlying hypotheses are correct.

By the time-consuming laborious manual step-by-step numerical integration of the equations, Hodgkin and Huxley were able to plot the membrane potential during the course of an action potential and the behavior of the state variables n , m , and h . From these plots, it is possible to understand the details of action potential generation. Now, anyone with a little programming experience can reproduce and study the Hodgkin-Huxley model. The model has also

been implemented as an example or tutorial in nearly every neural simulator package.

The examples given here were generated with the GENESIS simulator (Bower and Beeman 1998, 2003) using the “Squid” Tutorial that was developed by Mark Nelson (Nelson and Rinzel 1998). The screen images are taken from a set of online lecture notes by Beeman (2008).

Reproduction of the Voltage Clamp Experiments

Figure 4 shows screen images from a GENESIS simulation of a voltage clamp experiment. Here, the membrane potential is held at the resting potential for 10 ms, then rapidly raised to 50 mV above the rest potential, and held for 20 ms before returning to the rest potential. In accordance with

the original Hodgkin-Huxley conventions, voltages are measured in mV with respect to the resting potential of 0, and outward ionic currents are plotted as positive.

The plots at the *UPPER LEFT* show both the “command voltage” that is applied to the voltage clamp circuitry and the resulting membrane potential. A step from the resting potential of 0–50 mV is applied after 10 ms. Note the slight difference between the two plots at the top of the step. The simulated voltage clamp circuitry follows the behavior of that used in the experiments and cannot change the membrane potential instantly.

The *LOWER LEFT* plot shows the injection current used to maintain this voltage. The very sharp initial spike is due to the large current needed to quickly charge the membrane capacitance to the clamp voltage. This can be seen from

H

Hodgkin-Huxley Model, Fig. 4 Simulation of a voltage clamp experiment using the Hodgkin-Huxley model. (Reproduced from Beeman (2008) with permission from the author)

Eq. 1, where dV_m/dt is nearly infinite during the voltage step. It is followed by an inward Na current, shown as a negative current here, then an outward K current.

The channel conductance plots at the *UPPER RIGHT* reveal a rapid rise in the Na conductance, followed by a slower decay as it becomes inactivated. The K current has a much slower activation and no inactivation. There is no decay until the voltage is dropped back to zero. These conductance changes result in the channel currents shown in the *LOWER RIGHT* plots. Because the Na equilibrium potential is greater than the resting potential, the Na current flow is inward (negative). The superposition of these two currents plus the initial capacitive current gives the injection current shown at the *LOWER LEFT*.

In an actual experiment, the currents would be measured directly, separating the K current from the total current by blocking or disabling the Na current. It would then be possible to calculate the conductances, which are plotted here. In the simulation, it is done the other way around.

From the values of the conductances the channel activation and inactivation variables can be calculated and plotted. Figure 5 shows a window from the Squid Tutorial that plots these during the voltage clamp.

Notice the value of m^3 at the resting potential and the time behavior during the steps to 50 mV and back down to rest. Initially, there is a balance between the inward Na current, the outward K current, and the leakage current. At the resting potential, m (black) is small, and h (red) is fairly large. Thus, m^3h is small, but nonzero. The

K activation n (blue) is moderate in size, but is also small when raised to the fourth power.

At the start of the voltage step, the depolarization causes m to increase as the Na channels open. After about 2 ms, the Na conductance inactivates and h decreases. While this is happening, the K conductance activates and n increases, leveling off to a steady value.

At the end of the pulse, n steadily declines toward its resting value, the Na activation rapidly drops to its original value, and the inactivation slowly returns to its original value. Note that the sodium inactivation and the potassium activation take much longer to reach their steady-state values than the sodium activation.

The key to understanding the role of these currents in the production of action potentials is to keep in mind the way that the steady-state values of the activation and inactivation variables depend on voltage and the relative magnitudes of their time constants for reaching steady state. Figure 6 shows a plot of these variables and their voltage-dependent time constants for various clamp voltages. In this plot, the resting potential is taken as -70 mV, instead of zero.

Notice that although the time constants depend strongly on voltage, the time constant for the Na activation variable m is about an order of magnitude less than that for the Na inactivation h and the K activation n throughout the entire range. This means that during an action potential, when the voltage is high and m is large, and h is supposed to be small, it will take a while for h to decrease. Also, it will take n some time to become large and contribute to the opposing K current. If it were not

Hodgkin-Huxley Model,

Hodgkin-Huxley Model, Fig. 6 Plots of the steady-state activation variables and time constants as a function of clamp voltage. (Reproduced from Beeman (2008) with permission from the author)

for the slower behavior of h , m^3h would be close to zero after the start of depolarization from -70 mV, and it would never be large enough to give the Na conductance needed for an action potential to form.

Post-Inhibitory Rebound

Hodgkin and Huxley's reconstruction of the action potential during a depolarizing current injection was an impressive test of the model. An even more interesting experiment is their recreation of the *anode break* or *post-inhibitory rebound* phenomenon which had been observed in squid axons after a hyperpolarizing current pulse.

Figure 7 shows plots from a simulation in which a brief current pulse of -0.1 microamperes is applied after 10 ms and held it for 20 ms. What behavior would you expect?

The plot of the membrane potential (*UPPER LEFT*) shows the typical curve for charging a capacitor with a negative current during the hyperpolarizing pulse. It starts to discharge at the end of the pulse, but instead of leveling off to the resting potential, we see a full-blown action potential, followed by hyperpolarization and then a return to the rest potential.

The channel conductance plots (*UPPER RIGHT*) show the conductances that one associates with an action potential – there is a sharp peak in Na conductance, followed by a broader delayed peak in the K conductance. This causes an

outward flow of current which terminates the action potential and causes the hyperpolarization. Many people find this result surprising. How can an inhibiting (hyperpolarizing) current produce an action potential if lowering the membrane potential causes the channel activations to decrease?

The plot of the activation and inactivation parameters (*LOWER RIGHT*) provides an explanation of what is happening. Before the hyperpolarizing pulse, the steady-state resting potential value of the Na activation parameter m is fairly low. The inactivation parameter h is moderately high, but the Na conductance is proportional to m^3h , so it is small and a small Na current flows into the compartment. n is small (about 0.35), so n raised to the fourth power is relatively small, and there is a slight K current in the opposite direction of the Na current.

From 10 to 30 ms, during the pulse, the cell becomes hyperpolarized, and m gets even smaller, becoming essentially zero. Although h increases, the resulting Na current is nearly zero.

At 30 ms, when the pulse has ended, the Na activation parameter m rapidly starts to increase toward its original small value. However, when it gets there, h is still very large, because of its much larger time constant for reaching its final value. This causes an increase in the Na conductance, which raises the membrane potential and allows m to increase even more. Near the peak of the action potential, h has finally decreased, and the K activation parameter n (in blue) has built up, so the action potential ends. The large value of n , and the resulting outward flow of potassium ions,

Hodgkin-Huxley Model, Fig. 7 A hyperpolarizing pulse produces anode break excitation. (Reproduced from Beeman (2008) with permission from the author)

accounts for the hyperpolarization following the action potential.

Refractory Period

Understanding this period of hyperpolarization is the key to understanding the *refractory period*, which was also analyzed by Hodgkin and Huxley. An examination of the plot of the activation state variables after the end of the action potential shows that shortly after the end of the action potential, the Na activation parameter rapidly decreases to near its resting potential value. But the inactivation parameter h is still very low, and the K activation parameter n is relatively high. It takes about another 10 ms before they get back to their original values. This interval is called the refractory period.

What would happen if we applied a depolarizing pulse during the refractory period? Imagine what would happen if the pulses were at 5 ms intervals. Not only would it be hard to get enough Na conductance to raise the membrane potential above threshold, but there would be a large K current in the opposite direction, tending to keep the cell hyperpolarized. Experiments with the simulation will confirm that at least 10 ms is required between action potentials.

Biological Basis of the Hodgkin-Huxley Model

The biological basis for the model described by Figs. 1 and 2 is now well known and understood. But is there a biological basis for the Hodgkin-Huxley form of the conductance equations? In

their model, the fourth power exponent for K activation in Eq. 4 and the third power for Na in Eq. 9 were obtained from a best-fit approximation to conductance data. They provided an explanation, but cautioned (Hodgkin and Huxley 1952d): “For the sake of illustration we shall try to provide a physical basis for the equations, but must emphasize that the interpretation given is unlikely to provide a correct picture of the membrane.”

They went on to assume that potassium ions can only cross the membrane when four similar particles occupy a certain region of the membrane. n represents the fraction of the particles in a certain position and $(1 - n)$ the fraction that are somewhere else. Then, Eq. 5 may be interpreted as a rate equation for the transition between these two states. n^4 would then be the probability that all gating particles are in the appropriate positions. They explained the Na conductance in similar terms, assuming that G_{Na} is proportional to the number of sites on the inside of the membrane which are occupied simultaneously by three activating molecules, but are not blocked by an inactivating molecule. The rates of transition between these states are given by similar rate equations for m and h .

At the time, very little was known of the nature of the cell membrane. It is notable that Hodgkin and Huxley did not use the word “channels” to describe the selective conductivity for Na and K.

During the 1960s and 1970s, Hille, Armstrong, and others introduced the idea that the two currents are carried by specific ion channels and proposed models for their ion selectivity and function. However, there was no information available at that time on the actual structure of the proteins that form the channels through the lipid membrane of the cell.

► “Patch Clamp Techniques” have provided detailed information about the response of single channels to depolarization. Measuring the current from individual channels revealed the all-or-none opening of voltage-gated channels. The continuous values of conductance predicted by the Hodgkin-Huxley model are produced by the

average behavior of very many single-channel openings and closings. More recently, Markov models (► “Markov Models of Ion Channels”) of channel dynamics have been developed that are suitable for simulations when the number of channels in a region is small enough that the fluctuations in average conductance become important.

There has been considerable progress in our understanding of the structure and function of the sodium channel, summarized in a recent review by Caterall (2012). Through the 1970s, several laboratories used neurotoxins to modify channel conductance and to identify the protein subunits of the Na channel. X-ray crystallographic and other structural analyses have now been applied to membrane proteins with a resolution down to the size of single atoms. Cloning and DNA sequencing the subunits of Na channels have provided another tool. Genes for most of the major channels have been cloned or sequenced. This information has been used to create models of the different channel proteins and to study the effects of alterations of their structure.

As a result of these studies of the Na channel protein, the voltage-dependent activation is understood in terms of the outward movement of identified gating charges, the “gating particles” of Hodgkin and Huxley. The mechanism for fast inactivation is also now understood, with functional and structural evidence for the closure of a fast inactivation gate. Although the details are much more complex than envisioned by Hodgkin and Huxley, and the “particles” are neither identical nor independent, the Hodgkin-Huxley paradigm of a small integer number of gating particles controlling the passage of ions was essentially correct.

Attractor neural network; Binary neural network; Equilibrium neural network; Recurrent neural network

Definition

Hopfield model was originally introduced as the representation of a physical system, whose state in a given time is defined by a vector $\mathbf{X}(t) = \{X_1(t), \dots, X_N(t)\}$, with a large number of locally stable states in its phase space, namely, $\mathbf{X}_a$, $\mathbf{X}_b, \dots$, also called *attractors*. Starting from some initial condition within the basin of attraction of one of these minima, that is, $\mathbf{X}(0) = \mathbf{X}_a + \Delta$, the dynamics leads the system toward this minimum, that is, $\mathbf{X}(t \rightarrow \infty) \approx \mathbf{X}_a$. The model provides a rule to convert any prescribed set of system states, the so-called *memory states*, into some of these locally stable states that now carry predefined information. This procedure allows the use of the model as a general content addressable memory system. The way the system reaches one of these memories from some initial state, which falls within its basin of attraction, then determines the so-called *associative memory process* (see Fig. 1b).

Detailed Description

In the original article where the model is proposed (Hopfield 1982), the state of the physical system

Hopfield Network, Fig. 1 (a) Scheme representing a Hopfield neural network where the processing devices or neurons are represented by open circles with states defined by V_i and symmetric connections among neurons are represented by bidirectional arrows. (b) Cartoon representing a hypothetical phase space for the Hopfield

network with a set of attractors states (black circles) and their corresponding basins of attraction separated by dashed lines. The curved arrows represent possible trajectories to reach the attractors from some given initial conditions

H

is defined as the state of N processing devices or *neurons*, each one having two possible states, namely, $V_i = 1$ (representing a firing neuron at maximum rate) and $V_i = 0$ (which represents a not firing neuron). The instantaneous state of the system then is defined by the vector $\mathbf{V}(t) = \{V_1(t), \dots, V_N(t)\}$ being, therefore, 2^N possible states of this type. When two neurons i and j are connected, it says there is a *synapse* among them, and the strength of such connection is defined as T_{ij} which, therefore, represents the state of such synapse. If the connection is not present then $T_{ij} = 0$. This defines the model as a neural network (see Fig. 1a). Moreover, the model assumes that the connection strengths T_{ij} include some information concerning a particular set of system states $\mathbf{V}^s$, $s = 1, \dots, n$, through the *storage prescription* (also known as learning rule)

$$T_{ij} = \sum_s (2V_i^s - 1)(2V_j^s - 1) \quad i \neq j \quad (1)$$

$$T_{ij} = 0 \quad i = j.$$

With this prescription, each neuron is connected to others neurons in the network except itself defining the so-called *fully connected network* or a *recurrent network*. The model also assumes that for each neuron there is a fixed threshold U_i for firing, so the dynamic of the physical system becomes

$$V_i = 1 \quad \text{if} \quad \sum_j T_{ij} V_j > U_i$$

$$V_i = 0 \quad \text{if} \quad \sum_j T_{ij} V_j < U_i \quad (2)$$

where the sum $\sum_j T_{ij} V_j$ is also referred as *local field*. When the model is used to study biological systems such as a neural medium, the local field is interpreted as the *synaptic current* received by a postsynaptic neuron connected with N presynaptic neurons with T_{ij} being the effectiveness of synapse (i, j) and therefore related to its synaptic conductance. The precise form of T_{ij} given in the prescription (1) can be related with modifications in time of the synaptic strength during *pairing* or training experiments which define the so-called Hebbian learning (Hebb 1949). More precisely, after the training of a particular activity state $\mathbf{V}^s$, the activities $V_i^s(t)$ and $V_j^s(t)$ of two neurons linked by a synapse induce a modification of the maximal conductance of this synapse in an amount

$$\Delta T_{ij} \propto \left[(2V_i^s(t) - 1)(2V_j^s(t) - 1) \right]_{\text{average}},$$

where the average is over the past history of both neurons. Note that the modification is positive if the training of the state s implied a positive correlation between the activities of both neurons (both

are firing) and negative on the contrary (one neuron is firing and the other is silent).

The Updating Scheme

In the original version of the model, the dynamics of each neuron is chosen to be asynchronous, random, and deterministic (i.e., in absence of noise). More precisely, each time step, a neuron is chosen at random (or using a predefined sequence) within the population and updated deterministically using rule (2). This type of neuron update is also known as *sequential updating* (Peretto 1992). There are, however, other types of updating schemes often used in the literature such as the updating of all neurons synchronously each time step, also known as *parallel updating* (Peretto 1992), or each time step choosing at random a subset of neurons within the population and updating them synchronously, also known as *hybrid updating* (see, for instance (Torres et al. 2008)). Different updating schemes determine different ways of convergence of the system toward its steady state.

Memory Capacity

In its pioneering work, Hopfield numerically computed that there is a maximum number n_c of network states V° that can be stored in network according to the prescription (1) and retrieved without severe errors. This number scaled with the size of the network as $n_c \approx 0.15 N$ for networks sizes ranging from $N = 30$ to 100 neurons. To obtain this number, Hopfield assumes that the network stored unbiased random patterns. Posterior numerical simulations of larger Hopfield networks and its extrapolation to $1/N \rightarrow 0$ resulted in a value of $n_c \approx 0.14 N$ (Volk 1998) which agrees with a theoretically value of $n_c = 0.138 N$ obtained within a statistical physics mean-field approach (Amit et al. 1987). This memory capacity can be increased assuming some conditions over the network topology and the stored patterns.

Hamiltonian Description

The Hopfield model admits a Hamiltonian description assuming that the connection strengths are symmetric $T_{ij} = T_{ji}$. In this case, one can define an energy function

$$H(\mathbf{V}) = -\frac{1}{2} \sum_{i \neq j} T_{ij} V_i V_j + \sum_i U_i V_i \quad (3)$$

describing the configurational state of the network, and which is isomorphic to the well-known long-range Ising Hamiltonian in the presence of a magnetic field when $T_{ij} = T_0 \forall ij$ and $U_i = U \forall i$. Within this framework, the term $\sum_j T_{ij} V_j - U_i$ is interpreted as the energy per neuron and it drives the dynamic of the neuron. That is, when a particular neuron i in the network changes its state according to the rule (2), there is a change in the energy of the network given by

$$\Delta H_i = -\Delta V_i \left(\sum_j T_{ij} V_j - U_i \right)$$

which implies (3) to be a monotonically decreasing function and, therefore, that the changes in the state of the network will occur until a local minimum in $H(\mathbf{V})$ is reached. This framework also allows to study the steady-state collective properties of the model using the statistical physics techniques by assuming that the network is in equilibrium with a thermal bath at temperature T that causes stochastic fluctuations of the neuron states around an equilibrium state defined by $H(\mathbf{V})$.

Definition

In human stick balance intermittency is observed (Fig. 1). Here intermittency denotes the random alternation between phases with extremely low movement amplitudes and phases with high

Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights, Fig. 1 A stick balanced at the fingertip

movement amplitudes. This type of intermittency is characterized by power laws in the distributions of corrective movements in real stick balancing and in virtual stick balancing (i.e., balancing an unstable target on a computer screen). These observations are commonly seen as evidence which contrasts neurological control from standard engineered controllers.

Detailed Description

Neural control mechanisms are subjected to the presence of time delays and random, uncontrolled fluctuations or noise. The interplay between noise and time-delayed control mechanisms can lead to the appearance of new phenomena which themselves are beneficial for the neural function. Here, attention is paid to the possible effects of fluctuations affecting the system parameters (Horsthemke and Lefever 1984) (parametric noise).

Tuning at the Edge of Stability: On-Off Intermittency in Human Stick Balancing

An important dynamical phenomenon produced by parametric noise is on-off intermittency (Platt et al. 1993) (OOI) that arises because of the fluctuating forcing of a control parameter across a stability boundary. OOI has been reported for the task of balancing a stick at the fingertip (Cabrera and Milton 2002). Stick balancing involves time-delayed control mechanisms in the presence of fluctuations. Detailed movement studies of the 3D trajectories of a balancing stick on the fingertip show that OOI allows for corrective movements on all timescales including those shorter than the physiological delay. This is interpreted as the first evidence showing how a control system can overcome the restrictions imposed by response times. From the stick trajectories, attention was paid to the quantity $\Delta z/l$, where Δz is the difference in the vertical coordinate of the upper and lower ends of the stick and l is the stick length. The dynamical behavior of a balanced stick is characterized by a highly fluctuating variable showing an intermittent temporal evolution (Fig. 2a) as evidenced by

a power-law dependence in the distribution of the times between two corrective movements (or laminar phases), δ with exponent $-3/2$ (Fig. 2b). The power spectra of the temporal series show also a power-law behavior but with exponent $-1/2$ (Fig. 2c). These exponent values are those expected for OOI (Platt et al. 1993; Venkataramani et al. 1996). The power law in δ implies that more than 98% of the times between corrective movements are shorter than the latency for the neural reflex involved in the balance control which was estimated around 100 ms (Cabrera and Milton 2002) or higher (Milton et al. 2016). Additional insights into the nature of the human neural control of stick balancing can be achieved modeling mathematically an inverted pendulum with time-delayed feedback in the presence of a parametric noise (Cabrera and Milton 2002). The model reads

$$\ddot{\theta} + \Gamma \dot{\theta} - q \sin \theta + R(t) \theta(t-1) = 0,$$

where θ is the angular deviation from the vertical, $R(t) \equiv R_0 + \xi(t)$ is a fluctuating restoring force

Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights, Fig. 2 (a) Temporal series for $\Delta z/l$ for a 62 cm stick balanced at the fingertip. The horizontal line is the threshold used to determine laminar phases δ . (b) Log-log plot of the power spectrum for the fluctuations in Δz characterized by a regime with power law of exponent

close to $-1/2$ (upper line). (c) Normalized laminar phase probability distribution, the triangles were obtained from a single realization, while circles describe the mean distribution from 48 realizations. The dashed line is a power law with exponent $-3/2$

with R_0 mean, and $\xi(t)$ is a zero mean Gaussian white noise, and other parameters are related to the stick physical characteristics. In this equation, $\theta(t - 1)$ accounts for the time-delayed responses where the latency time involved in the control, τ , has been normalized. A deterministic version of the model is characterized by the stability domain (with a half-moon shape) defined in the space of the variables concerning the human response (the intensity of the corrective term, R_0 , and the time delay, τ , as shown in Fig. 3a). Outside of the stability domain, the stick falls. For the values of (R_0, τ) depicted as points on the stability domain, results of integrating the model stochastic version can be seen at Fig. 3, right column. The numerical temporal series resembling the experimental one (Fig. 2a) is that obtained with (R_0, τ) tuned very close to the stability boundary (Fig. 2d). At this value, it is also possible to reproduce the power-law behavior observed in the experiment (not shown Cabrera and Milton 2002).

These findings suggest that the nervous system has an elegant solution to the stick balancing problem: (i) increasing maneuverability by tuning parameters very close to the instability (ii) where a parametric noise can give place to corrective

movements on all time scales including shorter than the time delay. These interesting results may have triggered further research and additional approaches to the problem of human stick balancing including intermittent control (Loram et al. 2011). Note that the latter denotes continuous control with discontinuous control forces, which may occur independently of intermittency, and with or without predictive control. Other recent research focused on sensory dead zones (Insperger et al. 2013) and on the related, but slightly different, problem of human upright standing control (Asai et al. 2013), among others.

A Lévy Flight in the Fingertip

Further insights in the stick balancing task have confirmed that changes in speed made by the fingertip are described by a truncated Lévy distribution (Cabrera and Milton 2004), defining a random walk known to be optimal for performing random searches (Viswanathan et al. 2011). Furthermore, changes in the subject skill level were related to changes in the Lévy distribution (Cabrera and Milton 2004), demonstrating that motor learning in continuous tasks can be characterized by changing distributions that reflect

Numerically determined deterministic stability domain for the Cabrera-Milton model and example time series for the parameter choices given by the solid symbols in (a) as shown, respectively, in (b), (c), (d), and (e)

sensorimotor skill acquisition (Cabrera and Milton 2004, Cluff and Balasubramaniam 2009; Fig. 4). More recent numerical and experimental research has shown that Levy noise improves stabilization when compared with Gaussian noise in the case of a stochastic parametric system with time delay as discussed above (Gutiérrez 2015; Odonell 2015).

Virtual Stick Balancing

Virtual stick balancing (VSB) facilitates data acquisition and setup manipulations compared to real stick balancing. In a typical setup, a cursor C and a target T are displayed on a computer screen (Fig. 4). C is controlled by the subject's hand movements. T is moved by the computer according to an unstable dynamics of first or second order. Subjects are typically told to keep C and T as close together as possible. Task variations include, for example, keeping T on the screen as long as possible. Input devices include, for example, the computer mouse (Bormann et al. 2004) and the manipulandum (Mehta and Schaal 2002).

Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights, Fig. 4 How the probability distribution of the speed changes in the fingertip is modified by learning for a subject balancing a 62 cm stick on the fingertip. As the subject get skilled in the balancing task, the tail of the distribution gets broad (for details, see Cabrera and Milton 2004)

While this task is very similar to real stick balancing, there are some differences: VSB involves only visual feedback about the target, while balancing a real stick on the fingertip can involve additional haptic feedback. Furthermore, movements in real balancing are limited, for example, by the length and inertia of the subject's arm, while in VSB additional limitations include the size of the screen, the movement dimensionality, and range of the input device, or the latency of the setup.

VSB time series exhibit power laws in the spectrum (Fig. 5a) similar to those observed for real stick balancing (Bormann et al. 2004). Furthermore, VSB has been performed with different task difficulties (Milton et al. 2013). Hard tasks are comparable to balancing a stick which is shorter than 1 m. In easier tasks, subjects are able to control the target for minutes. While the variance in easier tasks is smaller than for the hard task, the shape of the distribution can be more heavily tailed (Milton et al. 2013). Here, the cumulative distributions of large distances y in between C and T (control errors) are well described by a power-law $P(y > Y) \propto |y|^{-\xi}$ with an exponent ξ in between 2 and 4 (Patzelt et al. 2007; Fig. 6). An apparent truncation for the largest events in each time series is caused by temporal correlations (see supplement to Patzelt and Pawelzik 2011): subsequent measurements are not independent.

The power-law distribution of control errors suggests that parametric noise is adjusted such that the system even in simple tasks appears to be close to a critical point: self-similar fluctuations

Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights, Fig. 5 A common virtual balancing setup: subjects control a mouse cursor C and have to catch a target T which is controlled by the computer. C and T can be thought of as the projections of the positions of the two ends of a stick onto the horizontal plane

H

in y over up to three orders of magnitude (mm to m) are observed. This hypothesis might explain why Human VSB control parameters are often identified to be close to the edge of stability (see e.g., Matsumoto et al. 2018 for a recent example). However, it raises the question why extreme fluctuations which pose the risk of losing control are not avoided.

A suggested cause of the parametric noise is an online estimation of system parameters. The motivation for this model is evidence that certain balancing tasks are predictive (Mehta and Schaal 2002) and that humans are often capable of adapting to quickly changing environments (Patzelt et al. 2007). The model controller at each point in time makes a short-term prediction of where T is going to move. Then, it moves C in the same direction slightly faster in order to catch T (Fig. 6). The predictor compensates for reaction delays which for subjects were estimated significantly above 150 ms (Patzelt and Pawelzik 2011) and sometimes even above 300 ms (Bormann et al. 2004). The distinctive feature of this model compared to standard views on the action-perception cycle (Wolpert and Ghahramani 2000) is that the parameter of the forward model is an ad hoc estimation.

A predictive and highly adaptive controller as described above can run into an instability because successful control annihilates

observable information about the controlled system (Patzelt and Pawelzik 2011): it is only possible to predict where a stick is going to fall once it starts falling. This principle maps small control errors to large uncertainties about future dynamics and vice versa, thereby inducing self-similar fluctuations. It can be illustrated in a simple linearized example: consider a system with expected dynamics without control.

$$\dot{y}(t) = \vartheta y(t).$$

Assume that the system is observed at a given location y . Given noisy observations of y and $\dot{y}$ with respective probability distributions $p(y)$ and $p(\dot{y})$, the expected amount of information about the parameter.

$$\mathcal{I} = \frac{\langle y^2 \rangle}{\sigma_y^2}$$

vanishes if successful control moves the system towards the origin. Since $1/\mathcal{I}$ is a lower bound for the mean squared error of an unbiased estimator for ϑ , stabilization (minimizing $|y|$) evolves the system towards a critical point.

A complete balancing model involves a reaction time, an unbiased short-term parameter estimator, and an optimal forward model based on

Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights, Fig. 7 Standard models of the action-perception cycle include forward models allowing subjects to predict the future dynamics of their environment. If in addition parameters are estimated online on timescales

this prediction (Fig. 7). This model can reproduce the distribution of control errors and the power spectra of subjects in a virtual balancing task (Patzelt and Pawelzik 2011; Fig. 6). The kink in the power spectrum around 4 Hz corresponds to the reaction time of the controller. Controller memory and gain determine the scaling exponents. The model further suggests that power-law error distributions persist even after several hours of training because subjects minimize mean control errors by eliminating random local trends at the cost of rare, extreme errors. This is consistent with experimental results showing that humans can change this control strategy if incentivized (Patzelt 2014). Research involving other predictive control models also suggests that parameters at stabilities edge may reduce movement costs (Milton et al. 2016).

Human Connectome Project

Jennifer Stine Elam¹ and David Van Essen²

¹Department of Anatomy and Neurobiology, School of Medicine, Washington University, St. Louis, MO, USA

²School of Medicine, Washington University, St. Louis, MO, USA

Definition

The Human Connectome Project (HCP) is a major endeavor to map the neural pathways that underlie brain function and its variability in humans. The purpose of the HCP is to acquire and share data about the structural and functional connectivity of the human brain, the “connectome,” on the macroscopic scale ($\sim 1 \text{ mm}^3$ or greater) as analyzed using noninvasive neuroimaging in a large population of healthy adults (Van Essen and Ugurbil 2012).

Neuroimaging, behavioral, and genetic data being acquired by the HCP from 1,200 healthy adults will serve as a key resource for investigators in many fields, including neuroimaging, neuroanatomy, psychology, computational neuroscience, and network modeling. To facilitate data sharing, the HCP is developing an informatics platform comprised of the “ConnectomeDB” database for data storage, processing, and distribution and “Connectome Workbench,” a tool for data visualization and exploration.

Detailed Description

Origins of the HCP

With the goal of systematically examining human brain connectivity and its variability across the whole brain in large numbers of subjects with neuroimaging, in 2009 the NIH announced a request for applications for the Human Connectome Project. The NIH Blueprint for Neuroscience funded grants in September of 2010 to two consortia (<http://www.neuroscienceblueprint.nih.gov/connectome/>) that are taking complementary approaches. One is a 5-year grant to a consortium of ten institutions led by Washington University in St. Louis (WashU), the University of Minnesota (UMinn), and Oxford University (the “WU-Minn HCP Consortium”). This is a \$30 M effort to characterize human brain connectivity and function in 1,200 healthy subjects using four magnetic resonance imaging (MRI)-based modalities plus magnetoencephalography (MEG) along with extensive behavioral and genetic data. The second is a 3-year grant to a consortium led by Harvard/Massachusetts General Hospital and the University of California at Los Angeles focused on developing a “next-generation” 3 T MR scanner for diffusion imaging.

Overview of the HCP

The WU-Minn HCP Consortium began with extensive efforts over a 2-year period to refine and optimize acquisition and analysis methods. Data acquisition began in August 2012 on subjects drawn from a population of adult twins and their non-twin siblings, in the age range of 22–35 years. Each subject is assessed in a 2-day study visit at WashU that includes behavioral measures in a broad range of domains, blood draw for eventual genotyping, and multiple MR scanning sessions on a single, customized 3 T Connectome Scanner (Van Essen et al. 2012, 2013). A subset of 200 subjects are also being scanned at UMinn on a 7 T scanner, beginning winter 2013. For both the 3 and 7 T systems, advanced pulse sequences are used to acquire T1-weighted and T2-weighted

anatomical MRI, diffusion imaging (dMRI), resting-state fMRI (rfMRI), and task-evoked fMRI (tfMRI) scans. Seven tasks are included in the tfMRI scans aimed at identifying a maximal number of functionally distinct cortical parcels in a wide range of neural systems over the whole brain.

MEG is being acquired on a subset of 100 subjects at St. Louis University, including resting-state scans plus three task-evoked scans. MEG will provide data with higher temporal resolution

(milliseconds instead of seconds) at a coarser spatial resolution (centimeters vs. millimeters) than is available with MRI.

The HCP is advancing capabilities for analyzing brain connections capitalizing on the high-quality functional and structural image data being generated by the project. Innovative data processing and analysis pipelines are being developed and implemented as the data are collected. The data are being distributed at multiple stages of processing/analysis, giving users the ability to

choose the level of data on which to conduct their own analyses. HCP is also distributing the processing and analysis pipelines themselves, when fully vetted and finalized versions are available. This will enable users to run pipelines on data collected outside the HCP and directly compare it to the HCP data.

ConnectomeDB and Connectome Workbench

The HCP has built a suite of informatics tools to enable high throughput data collection, automated data processing and analysis, data sharing, and data mining and visualization (Marcus et al. 2013). A two-tiered database based on the XNAT database platform (Marcus et al. 2007) has been developed for managing and sharing large amounts of unprocessed and processed HCP data (expected to approach 1 petabyte by the end of the HCP). The HCP consortium manages data collection and quality control validation

using the private database IntraDB. Data are then moved to ConnectomeDB (<https://db.humanconnectome.org>), the HCP's externally accessible database, enabling data sharing, data mining, and discovery science by end users (Fig. 1). Customizations for the XNAT system employed by ConnectomeDB are available as pluggable modules that can be downloaded (<http://marketplace.xnat.org/>) and deployed on independent XNAT systems. In addition, the overall code for the HCP databases is open source and available on the Bitbucket version control system (<https://bitbucket.org/hcp>).

The Connectome Workbench (a.k.a. “Workbench”) brain surface and volume visualization platform has been developed to provide novel capabilities for viewing images and connectivity analysis results being produced by HCP (Fig. 2). Workbench has its origins in Caret software (Van Essen et al. 2001) but has been thoroughly redesigned with new features, many that accommodate the new CIFTI data format introduced for connectivity matrix data (<http://www.nitrc.org/>

H

Human Connectome Project, Fig. 2 Connectome Workbench GUI showing Story-Math language task activations on brain surfaces and volumes of an individual subject

projects/cifti/). The Workbench platform is comprised of an application with a graphical user interface for interactive display of data mapped to brain volumes or surfaces and “wb_command,” software run on the command line for performing various tasks related to handling and processing neuroimaging data for analysis and visualization. Workbench is open source and available for download at <http://humanconnectome.org/connectome/get-connectome-workbench.html>.

Hybrid Parameter Optimization Methods

Werner Van Geit

Blue Brain Project, EPFL, Lausanne, Switzerland

Definition

Hybrid parameter optimization (HPO) methods are search strategies that combine the strengths of different optimization algorithms to increase the performance of the overall parameter search process.

Detailed Description

Parameter optimization tends to be very complex, especially for the situations it is used for in computational neuroscience. Due to the many nonlinearities in neuronal systems and the large number of free parameters, the fitness landscapes tend to be highly dimensional and non-convex (Prinz et al. 2003; Achard and De Schutter 2006; Druckmann et al. 2007). Every optimization algorithm is optimal for certain shapes and sizes of the solution space (Achard et al. 2010). Unfortunately, the shape can change depending on the resolution one scans the parameters. On a macroscopic scale, the problem might look very non-convex with a lot of local minima, but close-ups around the optimal solutions could show a much more convex local environment.

The scientist who wants to use parameter optimization methods has to decide which algorithm to use. This implies having some knowledge about the shape of the parameter space. There will also be constraints on the amount of

computational resource available, so it is not only a question of finding the best values for the parameters but also a question of finding them as quickly and as efficiently as possible.

This is where hybrid optimization techniques can be beneficial. Instead of choosing one algorithm that could be suboptimal for some parts of the solution space, one combines different algorithms, sequentially or in parallel.

One example of a sequential hybrid approach would be to first apply a global search technique, like a genetic algorithm, to isolate a set of islands in the solution space that have a high fitness value, and then apply to these islands a local search algorithm, like downhill simplex (DS) method (Nelder and Mead 1965) to find the best solution for every island (Vossou et al. 2007).

When estimating neuron parameters, it can sometimes be beneficial not to give all parameters at once to a search algorithm, but rather to isolate known subproblems. The fitting process of the passive parameters (combined with typically the h-current) of a detailed neuron model does, e.g., involve much less nonlinearities. One could therefore fit these parameters first, possibly with a simpler optimization algorithm. Next these parameters can be fixed and a possibly more advanced algorithm can estimate the values for the active parameters (Roth and Bahl 2009; Keren et al. 2009).

Mitra et al. show a similar use case by combining gradient descent (GD) and DS methods (Mitra et al. 2013). In this study the GD algorithm was on its own not able to converge to the global minimum. When applying the DS method, the solution became however very dependent on the initial conditions. A hybrid algorithm that first runs the GD using just one part of the fitness function and then using that result as a starting point for the DS method overcame the disadvantages of the isolated algorithms.

Another class of hybrid optimization techniques involves the application of different algorithms in parallel. An example is an algorithm that on the fly tunes the mutation rates of a genetic algorithm based on some heuristic (Maeda and Li 2007).

Hyperpolarization-Activated Cyclic Nucleotide Gated Channels

Matthew F. Nolan

Centre for Integrative Physiology, University of Edinburgh, Edinburgh, UK

Synonyms

F current; H⁻ current; HCN channels
hyperpolarization-activated current; I_h; Q current

Definition

Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are membrane ion channels that are permeable to sodium and potassium ions. They open when the membrane potential hyperpolarizes and close when it depolarizes. This contrasts with the majority of voltage-gated ion channels, which open on depolarization and close on hyperpolarization. HCN channel gating can be directly modulated by cyclic nucleotides. At a molecular level, HCN channels have a structure similar to voltage-gated potassium channels. Individual subunits have six transmembrane domains and a reentrant pore loop but are distinguished by a cyclic AMP-binding domain located near to their C-terminus. Functional channels are formed by homomeric or heteromeric assembly of four subunits.

Detailed Description

HCN channels are an important and striking exception to the general rule that voltage-gated ion channels open in response to depolarization of a cell's membrane potential. Instead, HCN channels open when a cell's membrane hyperpolarizes and close when it depolarizes. Currents with these properties were first described in the heart and retina (Yanagihara and Irisawa 1980; Brown et al. 1979; Brown and DiFrancesco

1980; Attwell and Wilson 1980; Bader et al. 1979) and later found to be present in many central neurons (Halliwell and Adams 1982; Pape 1996; Robinson and Siegelbaum 2003; Biel et al. 2009). The unusual voltage dependence of these currents, which are often referred to as hyperpolarization-activated currents (I_h) (Hille 2001; Pape 1996; Robinson and Siegelbaum 2003), led to their also being called funny (I_f) (Brown et al. 1979) or queer (I_q) currents (Halliwell and Adams 1982).

Currents Through HCN Channels

HCN currents typically activate with a delay following hyperpolarization to potentials negative to approximately −50 mV. The current through HCN channels is mediated by both Na⁺ and K⁺. In physiological conditions, currents reverse polarity at potentials in the range of −20 to −50 mV (Pape 1996; Robinson and Siegelbaum 2003; Biel et al. 2009). The single channel conductance of HCN channels appears to be low, with an estimated value of approximately 1 pS (DiFrancesco 1986; Kole et al. 2006). Gating of HCN channels in response to changes in membrane potential is relatively slow. Activation time constants for HCN currents range from tens of milliseconds in some cells to greater than 1 s in others (Pape 1996; Robinson and Siegelbaum 2003; Biel et al. 2009). An instantaneous component of HCN channel activation has also been reported (Proenza et al. 2002). Elevation of intracellular cAMP shifts the voltage dependence of channel opening in a positive direction and accelerates channel opening and closing (DiFrancesco and Tromba 1988; Robinson and Siegelbaum 2003; Biel et al. 2009; Pape 1996).

The current through HCN channels (I_h) can be modeled using a Hodgkin-Huxley formalism with a single activation variable:

$$I_h = g_h m(V - E_h)$$

where g_h is the maximum conductance, V is the membrane potential, E_h is the membrane potential at which I_h reverses polarity, and m is the

activation variable, such that $\partial m / \partial t = \alpha(1-m) - \beta m$, where α and β are voltage-dependent rate constants for transitions between open and closed states of the channel. More complex gating schemes are required to account for delayed activation and cAMP modulation of I_h (Altomare et al. 2003; Wang et al. 2002).

Molecular Properties

In mammals, HCN channels are encoded by a family of four genes (Robinson and Siegelbaum 2003; Santoro et al. 1997, 1998; Ludwig et al. 1998, 1999; Vaccari et al. 1999; Seifert et al. 1999; Santoro and Tibbs 1999). Homologues of these genes have been identified in non-mammalian organisms, including sea urchin (Gauss et al. 1998), insects (Krieger et al. 1999; Marx et al. 1999), urochordates (Jackson et al. 2012), and the unicellular choanoflagellates (Cai 2012). Each gene encodes a protein with six transmembrane domains (S1–S6) and a reentrant pore loop. The membrane topology is similar to voltage-gated K^+ channels (Santoro and Tibbs 1999; Robinson and Siegelbaum 2003; Biel et al. 2009). Functional channels are formed from four subunits assembled as homomers or heteromers (Santoro et al. 2000; Chen et al. 2001; Ulens and Tytgat 2001). Just as for voltage-gated K^+ channels, the voltage sensor for HCN channels is in the S4 domain, which moves in an extracellular direction on depolarization (Vemana et al. 2004; Mannikko et al. 2002; Bell et al. 2004). Binding of cAMP relieves an inhibitory action of the cyclic nucleotide-binding domain (Wainger et al. 2001). Crystal structures of this domain identify mechanisms for the specificity of cAMP binding (Zagotta et al. 2003).

Diversity in the kinetics, voltage dependence, and sensitivity to cAMP of currents through HCN channels is achieved through several mechanisms (Santoro et al. 2000; Robinson and Siegelbaum 2003). Homomeric channels assembled from different subunits have distinct voltage dependence and sensitivity to cAMP (Ishii et al. 1999; Ludwig et al. 1999; Seifert et al. 1999; Altomare et al.

2003; Wainger et al. 2001; Santoro et al. 2000; Stieber et al. 2005; Mistrik et al. 2005). Heteromeric assembly of different subunits results in channels with properties typically intermediate between those of their constituent subunits (Altomare et al. 2003; Chen et al. 2001; Ulens and Tytgat 2001). Association with the accessory subunit protein Trip8b modifies the amplitude, kinetics, and voltage dependence of HCN currents (Santoro et al. 2004; Zolles et al. 2009). Alternative splicing of Trip8b provides further increases in the diversity of HCN current properties (Santoro et al. 2009; Lewis et al. 2009). Finally, modulation by a number of protein kinases enables further tuning of HCN currents (Pape 1996; Biel et al. 2009).

Cellular Functions

Three biophysical features of HCN currents are central to their cellular functions. First, the relatively positive reversal potential of HCN currents means that opening of HCN channels depolarizes the membrane potential. Second, as they open at relatively negative membrane potentials, HCN channels primarily influence subthreshold membrane potential activity. Third, because their kinetics are relatively slow, HCN channels oppose slow changes in membrane potential. This causes a characteristic sag-like response to current steps (Araki et al. 1961; Pape 1996). These features manifest in several distinct cellular functions. In some cells, for example, in the heart and thalamus, subthreshold activation of HCN channels contributes to pacemaking of rhythmic activity (Pape 1996). In other cells, for example, cortical pyramidal neurons, HCN channels control integration of synaptic responses (Magee 1998, 1999; Nolan et al. 2004; Robinson and Siegelbaum 2003; Biel et al. 2009). Other functions for HCN channels include promotion of membrane resonance by suppressing responses to low-frequency inputs (Nolan et al. 2007; Ulrich 2002; Hutcheon et al. 1996) and control of synaptic plasticity (Nolan et al. 2004; Tsay et al. 2007). Activity-dependent plasticity of HCN channels can modify these functions (van Welie et al. 2004; Fan et al. 2005).

Contributions to *In Vivo* Physiology, Behavior, and Disease

HCN currents contribute to pacemaking of the cardiac rhythm and acceleration of heart rate following sympathetic activation (DiFrancesco 1993; Biel et al. 2009). In the brain, direct evidence for HCN channel functions at a behavioral level comes from studies in which HCN genes are knocked out. These indicate roles for HCN1 channels in motor learning (Nolan et al. 2003), in spatial memory (Nolan et al. 2004), and in sensitivity to anesthetics (Chen et al. 2009). Pharmacological manipulations of HCN channels indicate further roles in working memory (Wang et al. 2007). There is evidence for major roles of HCN channels in several forms of epilepsy (Ludwig et al. 2003; Shah et al. 2013; Noam et al. 2011), as well as in neuropathic pain and cardiac disorders (Biel et al. 2009; Baruscotti et al. 2010), while reduction of HCN currents may promote antidepressant behavior (Lewis et al. 2011; Kim et al. 2012).

Definition

This entry refers to Bayesian methods (Gelman et al. 1995; Bishop 2006) for making inferences about neural activity from brain imaging data. This includes data from functional magnetic resonance imaging (fMRI) (Huettel et al. 2009), magnetoencephalography (MEG), and electroencephalography (EEG) (Luck 2005). These data are unique in neuroscience in that they allow, through noninvasive methods, relations to be studied between the large-scale activity of the brain and human behavior. Statistical aspects of microscopic neural activity can be estimated through Bayesian inversion of appropriate mathematical models. The methods described below have been applied to the study of a wide range of human brain functions from low-level sensory processing and sensorimotor integration to studies

Imaging Analysis, Bayesian, Fig. 1 Brain mapping identifies regions where experimental effect sizes are significantly nonzero (*orange*), as identified using the posterior distribution. Brain connectivity then explains activity in a set of regions using differential equation models with directed connections. For brain mapping, the parameters of

interest, θ , are regional activities, and for brain connectivity, they are directed pathways (*blue*). Both approaches can be applied to data, y , from *fMRI* or *MEG/EEG*. For *fMRI* this requires Bayesian inversion of a forward model describing a temporal convolution and for *MEG/EEG* a forward model describing a spatial mapping

of memory, emotion, and decision making (Friston et al. 2007b; Fig. 1).

Detailed Description

In what follows $N(x; m, V)$ denotes a multivariate Gaussian density, with mean m and covariance V , over the random variable x . Bayesian inference is used to transform prior distributions over parameters describing neuronal activity, $p(\theta)$, into posterior distributions, $p(\theta|y)$, based on neuroimaging data y .

Brain Mapping

MEG sensors, placed over the head, detect changes in magnetic fields due to changes in underlying neuronal currents. EEG electrodes, in contact with the scalp, detect voltage differences due to these same currents. For both MEG and EEG data (MEG/EEG), we can capture the relation between neuronal sources, θ , and measured signals y as a linear relation $y = L\theta$ where L is a lead field matrix derived from Maxwell's equations (Baillet et al. 2001).

These observations are assumed to be corrupted with Gaussian noise having covariance V_y . This leads to the statistical model

$$\begin{aligned} p(y|\theta) &= N(y; L\theta, V_y) \\ p(\theta) &= N(x; 0, V_\theta) \end{aligned} \quad (1)$$

Because there are many more potential brain sources (thousands) than MEG/EEG sensors (tens or hundreds), the prior $p(\theta)$ must provide sufficient constraints so that the sources can be recovered. MEG/EEG source reconstruction algorithms, such as “minimum norm,” “low-resolution tomography (LORETA),” or “multiple sparse priors (MSP),” are differentiated by their priors and estimation algorithms for approximating the posterior $p(\theta|y)$ (Wipf and Nagarajan 2009; Litvak et al. 2011).

fMRI detects changes in neuronal activity via changes in hemodynamics and the differential magnetic properties of oxygenated versus deoxygenated blood. This is known as the blood oxygen level-dependent (BOLD) effect (Huettel et al. 2009). Given the time courses of experimental conditions, we can predict the resulting fMRI

signals via temporal convolution with canonical response profiles (Friston et al. 2007b). The result of this convolution step can be captured in a design matrix X . The fMRI signal is then modeled as

$$\begin{aligned} p(Y|\theta) &= \prod_n N(y_n; X\theta_n, V_y) \\ p(\theta) &= \prod_k N(\theta_{k\cdot}; 0, V_\theta^k) \end{aligned} \quad (2)$$

where y_n is the fMRI time series at the n th spatial location, θ_{kn} is mean neuronal activity for experimental condition k at voxel n , and the prior covariance V_θ^k enforces local spatial smoothness constraints on the estimate of the k th neuronal response (Woolrich 2012). Inference about neuronal effect sizes can then be made from the posterior and displayed using posterior probability maps (PPMs) (Friston et al. 2007b). Bayesian methods also allow one to infer that a region has not activated (Woolrich 2012).

Brain Connectivity

Interactions among brain regions can be studied using a variety of statistical tools including structural equation modeling, regression methods, and principal or independent component analysis (Friston et al. 2007b). Studies of brain connectivity with fMRI that take a dynamical systems approach typically model time series, y , from a small number of regions (less than ten). These regions are selected based on previous analyses of imaging data or from knowledge of systems neuroscience (Kandel et al. 2000; Frackowiak et al. 2003).

$$\begin{aligned} p(y|\theta) &= N(y; g(x, \theta), V_y) \\ \dot{x} &= \left(A + \sum_i u_i B_i \right) x + Cu \\ p(\theta) &= N(x; m_\theta, V_\theta) \end{aligned} \quad (3)$$

where $\theta = \{A, B, C, h\}$ are model parameters. Here, x is a vector of neuronal activity in multiple brain regions, $\dot{x}$ denotes the time derivative, and

u is a vector of experimental stimuli. Connectivity is characterized by a set of “intrinsic connections,” A ; input connections, C ; and modulatory connections, B . Here B specifies which intrinsic connections can be changed by contextual variables involving, for example, changes in attentional or instructional set. The overall connectivity pattern is a scientific hypothesis about the structure of the large-scale neuronal network mediating the underlying sensorimotor or cognitive function. Such hypotheses can be compared using Bayesian model selection (Penny et al. 2004).

In the above model, neuronal activity gives rise to fMRI activity by a dynamic process described by an extended Balloon (Buxton et al. 1998) and BOLD signal model. This takes the place of the linear convolution models used in mapping studies and has the advantage of accommodating, for example, nonlinear hemodynamic saturation effects. These models are not routinely used in mapping studies due to the computational expense of fitting them at large numbers of voxels. The overall dynamic model involves a set of hemodynamic state variables, state equations, and hemodynamic parameters, h . Together these equations describe a nonlinear process, $g(x, \theta)$, that converts neuronal activity into the BOLD signal.

For MEG/EEG data, dynamical connectivity models are again usually based on activity in a small number of regions

$$\begin{aligned} p(y|\theta) &= N(y; Lx, V_y) \\ \dot{x} &= f(x, u, \theta) \\ p(\theta) &= N(x; m_\theta, V_\theta) \end{aligned} \quad (4)$$

where x is a vector of neuronal activity. This activity is driven by experimental perturbations u according to a differential equation with parameters θ . Models of event-related fields/potentials (Luck 2005) are based on variants of the Jansen-Rit model (David et al. 2006) for describing the activity of multiple cell populations within a single cortical unit. Multiple cortical units are then connected together using anatomically realistic connection rules (Felleman and Van Essen 1991) to form large-scale networks. Priors over model

parameters constrain, for example, synaptic time constants to physiological ranges. Usually, the most interesting components of the posterior distribution are those that describe changes in the long-range excitatory connections among regions (Litvak et al. 2011).

Model Inference

Bayesian inference for the above models is based on the standard corpora of approximate inference methods (Gelman et al. 1995; Bishop 2006). Due to the size of most neuroimaging data sets, with data at potentially thousands of spatial positions and hundreds of time points, deterministic methods such as variational Bayes (Bishop 2006; Friston et al. 2007a) are most often used. Methods have been developed to make inferences about families of models and effects that are consistent over a group of subjects.

Synonyms

[Electron microscopic imaging](#); [Electron microscopy](#)

Definition

Electron microscopy is the method by which electrons interact with a sample and are collected to

detect a signal or change in sample density. This density is then either transferred onto a photographic plate or digitally recorded to create an electron micrograph.

Detailed Description

Electron microscopy is an imaging technique used by those who require a higher resolution than conventional light microscopy allows. Electrons are emitted from a filament tip and are accelerated and focused into a beam that targets and interacts with a sample. Electrons are then collected, and an image is recorded based on the results of those interactions.

Applications

Electron microscopy is often applied to samples of either biological origins or inorganic materials, including metals and crystals. Biological specimens include microorganisms, fixed tissue samples, and small structures, ranging down to large molecules or proteins.

Electron microscopy plays a crucial role in neural circuit reconstruction because it is the only imaging method by which individual processes in densely stained tissue can be imaged and reconstructed at the necessary resolution of synapses. It is because of this necessity that multiple associated methods have been developed and applied to volumetric imaging through neural tissue, including focused ion beam electron microscopy (FIB-SEM), serial-section transmission electron microscopy (SS-TEM), and serial block-face scanning electron microscopy (SBEM).

Brief History

Electron microscopy is a young imaging technique, relative to light microscopy, due to the necessity of the development of high vacuums and electromagnetic lenses to focus the electron beam. The first electron microscopy lens was developed in 1926 by Hans Busch, and the first transmission electron

microscope came five years later in 1931, developed by Ernst Ruska and Max Knoll (Nobel Prize Foundation 1986). That same year, Reinhold Rudenberg patented the electron microscope. The first electron microscope, however, did not surpass the resolving power of the best light microscopes. That was developed 2 years later in 1933 for TEM by Ruska. The first SEM did not appear until 1937 when Manfred von Ardenne adapted raster scanning to the electron beam.

Types of Electron Microscopy

Transmission Electron Microscopy

Transmission electron microscopy (TEM) is a method by which thin samples, usually either positioned over a hole on a sample holder or spanning across a thin layer of Formvar film, are bombarded with an electron beam, and the resulting distribution of electrons is recorded on the opposite side of the thin section. In a transmission electron microscope (Williams and Carter 1996), the electrons are differentially transmitted through the sample based on heavy metal composition. Because heavy metals will prevent the passage of electrons, the resulting image shows an inverted image where electrons either passed through the sample or failed to do so.

Scanning Electron Microscopy

Scanning electron microscopy (SEM) does not rely on the use of thin sections. Rather, a sample is placed under an electron beam and electrons are recorded after interacting with a limited volume below the sample surface. Based on the voltage and current of the electron beam, the interaction volume of the beam with the sample can be manipulated to achieve the desired resolution, down to 0.4 nm with the Hitachi S-5500. Most scanning electron microscopes have a resolution limit that falls between 1 and 20 nm. SEM, unlike TEM, relies on raster scanning across the sample surface.

Scanning Transmission Electron Microscopy

Scanning transmission electron microscopy (STEM) is akin to a hybrid of SEM and TEM. The STEM method relies on the transmission of

electrons through a thin sample like TEM, but uses a raster scanning process across the sample, similar to SEM. This allows for the higher resolution of TEM with serial data collection.

Sample Preparation

Inorganic, conductive samples can be viewed directly in an electron microscope without the need for further sample preparation. Even inorganic materials that lack conductivity can be coated with thin conductive films to prevent charging artifacts. Most biological samples, however, require processing before the sample is suitable for visualization with an electron microscope. Such sample preparation steps include:

- Chemical fixation
- En bloc staining
- Cryofixation (for cryo-electron microscopy)
- Dehydration
- Embedding
- Sectioning or milling
- Section staining

Advantages

The most notable advantage offered by electron microscopy is its improved resolving power over visible light microscopy because electrons have wavelengths about 100,000 times shorter than visible light photons. Electron microscopy can achieve better than 50 pm resolution, whereas visible light microscopy is generally limited by diffraction to 300 nm.

Limitations

Most forms of electron microscopy only provide grayscale images which display heavy metal contrast in the sample. In combination with X-ray microanalysis, however, samples can be assessed for elemental composition based on emitted spectra while imaging, effectively creating a “color” electron micrograph.

Because an electron beam must pass through a vacuum to prevent the electrons from being

scattered due to interactions with air, specimens must also be placed in high vacuum. For biological samples, this can pose a problem and necessitates the use of chemical fixation, staining, and resin embedding for sample stability before imaging, and each process can induce unwanted artifacts in the sample.

Scanning electron microscopy is often liable to reductions in image quality due to charging-related artifacts. Because electrons can collect on the surface of a sample, those electrons can distort the path of primary, secondary, and back-scattered electrons, creating a warped image or preventing imaging entirely. It is possible to address this limitation by imaging nonconductive samples under low-vacuum conditions with water vapor or gas to discharge the sample surface by ions formed from interaction of the vapor or gas with the electron beam. Unfortunately, the low-vacuum conditions introduce additional noise into the image due to electron skirting.

Definition

Before specimens can be imaged for analysis using computational neuroanatomy techniques,

they must be properly prepared. Computational neuroanatomy encompasses a wide range of analysis, and correspondingly, a wide range of specimens can be analyzed. This discussion will focus on the preparation of specimens for high-throughput 3D microscopy technologies that are being rapidly developed. Methodologies that emphasize 3D molecular and morphological imaging, including ultrahigh-resolution electron microscopy imaging, provide complementary perspectives that can be applied to computational neuroanatomy. Through such analyses, it is possible to carry out detailed descriptions of local circuits that will help further elucidate neuronal function. These microscopy technologies together with high-performance computing power that continue to be improved enable data-driven, multi-scale modeling and simulation of large-scale neuronal circuits (such as the complete connectome of the mouse (Kleinfeld et al. 2011)).

Detailed Description

Introduction

Biological specimens to be analyzed using histological methods must be stabilized or preserved so that structural relationships can be maintained throughout the data acquisition phase. Biological specimens are obtained from living organisms, and specimens can consist of the entire organism such as insects (i.e., *Drosophila* or fruit flies), nematodes (i.e., *C. elegans*), or embryos (i.e., mouse or zebra fish embryos), or specimens can be the whole central nervous system (CNS, which includes the brain and spinal cord) taken from organisms such as mouse, rat, or adult zebra fish brain. Finally, samples also can include parts of the CNS taken from larger organisms including the human brain or spinal cord. High-throughput 3D analysis for computational neuroanatomy is still practically limited to analysis of specimens that are not much larger than a cubic centimeter (1.0 cm^3), which is the approximate size of an adult mouse brain. For this description, we will focus on the preparation of tissue samples that are no larger than 1.0 cm^3 , and we will describe specimen preparation that can be used for high-throughput 3D analysis.

Fixation

Once death of an organism has occurred, cellular integrity can no longer be maintained. Enzymes located within cells are released and start to act inside as well as outside the cells leading to tissue decay or destruction. The process of fixation stops the actions of these degradative enzymes on tissue/cellular components. It is important to prevent this process of “self-digestion” or “autolysis” from occurring because it will cause tissue morphology to change or become unrecognizable and severely autolyzed tissues also do not stain properly. Most common fixatives used today function to cross-link proteins together, which inactivates enzymes and maintains structural integrity of the cells and tissues. A wide range of factors can profoundly influence fixation, and these factors can be reviewed in the histotechnology textbook by Carson and Hladik (2009).

Common fixatives that are used are aldehydes such as formaldehyde (see Fig. 1a) and glutaraldehyde (Jaeger 2001). Less common fixatives that also can be used for specialized purposes are mercuric chloride (HgCl_2) and osmium tetroxide (OsO_4). All fixatives are toxic, but HgCl_2 and OsO_4 are especially so, and great care must be exercised if these fixatives are used. Formaldehyde is often used in the form of paraformaldehyde, which is a polymerized form of formaldehyde (Senda et al. 2005). Fixation should be carried out as rapidly as possible, and whole animal fixation is preferably carried out through perfusion (Mayerich et al. 2008a; Gage et al. 2012). Small pieces of tissue can effectively be fixed using immersion fixation, where the tissue, after it is excised from the body, is immersed in a fixative solution for an appropriate period of time (usually 48–96 h, depending on the volume of the tissue and the storage temperature – room temperature or refrigerated). After an appropriate time for fixation has elapsed, then the tissues can be stained.

Staining

Whole specimens can be stained either “en bloc” or using surface staining as sections of tissue are

Imaging, Specimen**Preparation, Fig. 1**

(a) Perfusion-fixed whole mouse brain, dorsal view. Brain was perfused with 10 % neutral-buffered formalin. (b) Perfusion-fixed whole mouse brain also stained en bloc with thionine. (c) Golgi-Cox-stained rat brain embedded in araldite resin. Scale bar = 1 cm and applies to all three figures

removed. Alternatively, individual neurons can be stained by injection of a dye such as biocytin (Jaeger 2001). En bloc staining refers to staining tissue components through the tissue while the tissue is still in one piece (Choe et al. 2011; Tapia et al. 2012). En bloc staining has been used to prepare electron microscopy samples for more than 30 years, but those samples have a typical volume of one cubic millimeter (1.0 mm^3), which is $1,000\times$ smaller than the volumes described in this protocol. However, en bloc staining methods have been developed using Nissl (see Fig. 1b) and Golgi-Cox staining for neurons (see Fig. 1c), using India ink to highlight blood vessels including capillaries, and heavy metal stains to produce high tissue contrast in serial sections used for field emission scanning electron microscopy (FESEM) (Jaeger 2001; Mayerich et al. 2008b; Choe et al. 2011; Tapia et al. 2012; Mikula et al. 2012). Nissl staining (typically cresyl violet or thionine dyes) stains neuronal cell bodies, while Golgi-Cox staining stains an entire neuron including the cell body as

well as its processes (dendrites and axon). India ink is used to fill the lumens of all blood vessels including the smallest blood vessels, the capillaries. Once staining is accomplished, the stained tissues can be processed for embedding in a resin that will allow the tissue to be sectioned.

Processing and Embedding

Synthetic resins such as Epon, Araldite, Spurr's resin, and LR White are commonly used to embed specimens so that thin sections ($0.5\text{--}1.0 \text{ }\mu\text{m}$) can be cut. After staining, tissues are dehydrated using graded alcohols and then immersed in an intermediate chemical (such as acetone or propylene oxide) that is miscible with alcohols and also with synthetic resins. The specimens are then infiltrated with the liquid resin before they are polymerized (see Fig. 1c). LR White is miscible with alcohol so an intermediate chemical is not needed during processing. Also, LR White does not quench fluorescence under normal processing

conditions, so it can be used for specimen prepared with fluorescence immunohistochemistry or green fluorescent protein (GFP) labeling (Luby-Phelps et al. 2003).

Independent Component Analysis of Images

Aapo Hyvärinen

Department of Computer Science, University of Helsinki, Helsinki, Finland

Synonyms

Independent component analysis of natural images; Olshausen-Field model; Sparse coding of natural images

Definition

Independent component analysis (ICA) is a general machine learning method for analyzing the statistical structure of data or signals. It is based on a linear generative model with statistically independent and non-Gaussian latent variables. In computational neuroscience, it can be applied on small patches (windows) of ordinary photographic images to model their structure. The result is that the independent components are similar to the outputs of simple cells in the primary visual cortex (V1). Thus, ICA of natural images provides an interesting theory to explain why the response properties (receptive fields) of simple cells in V1 are as they are: they are adapted to the statistical structure of natural images. This supports the more general hypothesis that the visual cortex constructs an internal probabilistic model of the world and codes the incoming input efficiently.

Detailed Description

Background and Motivation

In neuroscience, some of the most interesting questions to ask are the “why” questions: Why does a system in the brain function as observed? In vision, an important instance is the question of why the receptive fields in the visual cortex are what they are. The most common target here is V1 simple cells known to have spatially localized, oriented, band-pass receptive fields.

A long-standing hypothesis is that the visual cortex is adapted to the statistical (probabilistic) properties of the typical input. Intuitively speaking, typical images that the brain receives (“natural images”) are clearly not random white noise: locations next to each other tend to have similar luminance (grayscale value), and on a more abstract level, there are many contour-like continuities in the data. The hypothesis can be formulated from the viewpoint of coding images, in which case it is called *efficient coding*, where efficiency is taken in the sense of information theory. Alternatively, a Bayesian approach assumes that the visual cortex uses an internal *prior model* of natural input to perform probabilistic inference.

The main goal in ICA of natural images is to investigate the validity of this hypothesis. We can collect a large number of natural images as digital photographs and use ICA to analyze their statistical properties, or *natural image statistics*. If the results show similarities to known V1 properties, this can be seen as evidence supporting the hypothesis of adaptation to natural image statistics, which would provide a widely applicable theory on sensory processing.

ICA Model

Independent component analysis (ICA) is a general statistical (probabilistic) model of multi-dimensional data (Hyvärinen et al. 2001), but here we explain it in terms of image modeling. Denote by $I(x, y)$ the grayscale values of a natural image with x and y indicating the horizontal and vertical pixel location. While the images analyzed

are digitized in practice, we consider the grayscale values as continuous valued here and further assume that the mean grayscale value has been subtracted.

Since we model the brain’s probabilistic prior model about the structure of natural images (and, in practice, analyze a large collection of images), I is considered a random quantity, in particular a random vector. Denote by $A_i(x, y)$ the features (also called basis vectors) which are used to model the images; learning (estimating) these features is the main goal of ICA. The number of features, denoted by k , is fixed to be equal to the number of pixels in the basic model. The starting point in ICA is to express the data as a *linear superposition* of features:

$$I(x, y) = \sum_{i=1}^k A_i(x, y) s_i$$

where the components s_i are the coefficients of the features in a particular image. The components s_i are random variables, since they are different from one image to another, i.e., they are random in the same sense as I , while the A_i are nonrandom quantities, constant for all images. The linear model is illustrated in Fig. 1.

Once we specify the statistical properties (i.e., probability distributions) of the random variables s_i , we obtain a model which is *statistical* (or probabilistic) in the sense that it defines a probability distribution in the space of images I . The model is also *generative* in the sense that it describes how the data can be generated by first randomly generating the s_i and then linearly transforming them into I .

What distinguishes ICA from related statistical models are the statistical assumptions that we make on the s_i . In ICA, we assume that:

- The s_i are statistically independent from each other.
- The s_i have non-Gaussian distributions.

Especially the assumption of *non-Gaussianity* is important and sets ICA apart from classical methods such as principal component analysis (PCA) or factor analysis. Non-Gaussianity can

Independent Component Analysis of Images, Fig. 1 Illustration of linear modeling of the statistical properties of images. Given a set of large natural images, we sample small patches from them and express each as a linear superposition of the features which can be directly

plotted as image patches themselves. The goal is to learn the statistically optimal features. For illustration purposes, we have already plotted here some typical features learned by ICA

Independent Component Analysis of Images, Fig. 2 Illustration of sparsity, from Hyvärinen et al. (2009). In (a), samples are drawn from a sparse distribution and a Gaussian distribution of the same variance. The sparse variable takes more often very large values or values

very close to zero. In (b), a sparse probability density function (*solid*) is compared with the Gaussian one of equal variance (*dashed*). The sparse density has a prominent peak at zero and heavier tails (not very visible in this plot)

take many forms in general, but the fundamental form of non-Gaussianity in natural images is *sparsity*, i.e., the property that the s_i are very close to zero most of the time and only occasionally obtain very large values. Sparsity should not be confused with small variance; the difference is illustrated in Fig. 2.

Importantly, no assumptions on the A_i , other than their linear independence, are made in ICA. That is, the A_i are *not* assumed to be spatially localized or oriented or to have any specific spatial properties. Instead, the entire learning process is based on the statistical properties of the s_i . Any

specific tuning properties of the A_i are due to the statistical structure of images.

A fundamental theorem in ICA says that the model can be estimated by finding the linear features A_i which maximize the non-Gaussianity of the obtained components s_i (Hyvärinen et al. 2001). Such maximization of non-Gaussianity can be shown to be equivalent to different estimation principles such as maximum likelihood estimation, minimization of mutual information (statistical dependence) between the components, as well as maximization of information flow in a nonlinear network. (The last principle leads to an algorithm

which is often called the “infomax algorithm,” although infomax is in fact a general principle that can be used for other purposes than ICA.)

Due to the prominence of sparsity in natural images, ICA for images is essentially maximization of the sparsity of the estimated components. Thus, ICA is often called *sparse coding* in that context. The first application of ICA-like models on natural images was the Olshausen-Field sparse coding model discussed below.

Results on Natural Images

In practice, to keep the computations manageable, the natural images used in the model are very small, typically only a few hundred or thousand pixels; in other words, we model small parts of whole natural images, called patches or windows. In the simplest case we only model their grayscale values, although modeling of color and stereo images as well as video is equally possible.

Before applying the model to the data, the dimension is often reduced by principal component analysis (PCA) to reduce artifacts due to the limited pixel resolution. Such preprocessing does not change the theory in any way: The original pixels in the ICA model given above are simply replaced by the variables given by the principal components.

Results obtained by running ICA on a set of wildlife images are shown in Fig. 3. The features A_i have the characteristic properties of V1 simple cell receptive fields: they are spatially localized, oriented, and localized in spatial frequency. Alternatively, we could analyze the spatial filters which are obtained by inverting the generative model of ICA and more closely correspond to receptive fields; such spatial filters are essentially “sharper” versions of the features A_i , obtained by boosting their high-frequency content. Thus, we can consider that either the A_i or the spatial filters obtained by inversion provide a model of the linear receptive fields of simple cells, and the s_i model the actual responses. Due to the abstract nature of the ICA model, and linear models in general, the correspondence between the elements of the model and neuroscientific quantities is not quite unambiguously defined.

Independent Component Analysis of Images, Fig. 3 Some features A_i estimated by ICA from natural images, adapted from Hyvärinen et al. (2009). The size of the patches was 32×32 pixels, the number of patches was 50,000, and the PCA dimension was 256. ICA was performed by the FastICA algorithm. Each small square here corresponds to one feature A_i , which is plotted as an image patch itself; *gray* corresponds to zero, *white* to positive, and *black* to negative values. A given image patch can be constructed as a weighted sum of these A_i as in Fig. 1, where the weights s_i are different for each image patch

Extensions

The number of features can be larger than the number of pixels, which is called the case of an overcomplete basis. Furthermore, a Gaussian noise term $N(x, y)$ can be added to the generative model to model miscellaneous random effects. In both cases, the resulting features (basis vectors) are very similar to what is obtained by the basic model. Nevertheless, when the models are used for Bayesian inference, these extensions can change the results of the inference substantially. The original Olshausen-Field sparse coding model had a noise term and an overcomplete basis but is otherwise almost identical to the model described above. (The main further difference is that the Olshausen-Field model assumes the components to be sparse, while ICA allows different kinds of non-Gaussianity. However, for natural images, this hardly changes the results.)

As another extension, the components can be assumed to have limited statistical dependencies instead of being completely independent. Prominent examples of such modeling are topographic ICA (see ► [Topographic Independent Component Analysis](#)) and normalization models which explain extra-classical receptive fields including surround suppression (Simoncelli and Olshausen 2001).

Information Geometry as Applied to Neural Spike Data

Shun-ichi Amari
Laboratory for Mathematical Neuroscience,
RIKEN Brain Science Institute, Wako-shi, Japan

Definition

Information geometry studies invariant structures of a family of probability distributions. Such a family forms a Riemannian manifold together with a dual pair of affine connections (Amari

and Nagaoka 2000). Neural spike train data are of stochastic nature described by probability distributions. Information geometry is applied for elucidating the properties of spiking processes spread over a number of neurons as well as over time.

Detailed Description

Neuronal spike data are composed of a collection of binary variables $D = \{x_i(t)\}$, where $i = 1, \dots, n$ denote the numbers of neurons in an ensemble and t denotes the discrete time, $t = 1, 2, \dots, T$, such that $x_i(t)$ is 1 when a spike exists and 0 otherwise. The probability distribution governing $\{x_i(t)\}$ is searched for from observed data in order to elucidate temporal and spatial correlations of spikes. Since $x_i(t)$ are binary random variables, its distribution belongs to an exponential family, which is geometrically a dually flat Riemannian manifold.

Correlations and Joint Firing Rates

We first search for correlational structure in a neuronal ensemble, neglecting temporal aspects. Random variables are $\mathbf{x} = (x_1, \dots, x_n)$, where t is omitted. It is assumed that the data are generated subject to a probability distribution $p(\mathbf{x})$. Since there are 2^n firing patterns $\mathbf{x}$, the degrees of freedom of $p(\mathbf{x})$ are $N = 2^n - 1$. Hence, a probability distribution is specified by N -dimensional parameter, which forms a coordinate system in the manifold $S = \{p(\mathbf{x})\}$.

The log of probability $p(\mathbf{x})$ is expanded in a polynomial as

$$\log p(\mathbf{x}, \boldsymbol{\theta}) = \sum \theta_i x_i + \sum \theta_{ij} x_i x_j + \dots + \theta_{12\dots n} x_1 x_2 \dots x_n - \psi,$$

where ψ is the normalizing factor and the coefficients $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n; \theta_{12}, \theta_{13}, \dots, \theta_{n-1n}; \dots, \theta_{12\dots n})$ are used as a coordinate system to specify probability distributions in S . Since $\log p(\mathbf{x}, \boldsymbol{\theta})$ is linear in parameter $\boldsymbol{\theta}$, such a family is called an

exponential family of probability distributions and parameter θ is called a natural or canonical parameter.

Let us use another type of parameters given by

$$\begin{aligned}\eta_i &= E[x_i], \eta_{ij} = E[x_i x_j], \dots, \eta_{12\dots n} \\ &= E[x_1 \dots x_n],\end{aligned}$$

where E denotes expectation. These parameters $\eta = (\eta_i; \eta_{ij}; \dots; \eta_{1\dots n})$ form another coordinate system of S , called the expectation parameter or joint firing rate parameters, because

$$\begin{aligned}\eta_{i_1\dots i_k} &= E[x_{i_1} \dots x_{i_k}] \\ &= \text{Prob}\{x_{i_1} = 1, \dots, x_{i_k} = 1\}\end{aligned}$$

represents the joint firing rate of neurons $i_1, \dots, i_k$.

The two coordinate systems are hierarchically organized (Amari 2001), from the first-order parameters such as

$$\theta^1 = (\theta_1, \dots, \theta_n); \eta^1 = (\eta_1, \dots, \eta_n),$$

the second-order parameters

$$\begin{aligned}\theta^2 &= (\theta_{12}, \theta_{13}, \dots, \theta_{n-1n}); \eta^2 \\ &= (\eta_{12}, \eta_{13}, \dots, \eta_{n-1n}),\end{aligned}$$

until the n th-order parameter

$$\theta^n = \theta_{12\dots n}; \eta^n = \eta_{12\dots n}$$

We use indices I, J , etc. as θ_I or η_I to denote components of θ or η , where they run over $\{1, \dots, n; 12, 13, \dots, nn-1; \dots; 1\dots n\}$. Obviously, when n neurons fire independently, all the higher-order terms $\theta^2, \dots, \theta^n$ corresponding to the expansion of log probability vanish, and parameters $\eta^2, \dots, \eta^n$ are written in the product forms of firing rates η_i of individual neurons.

Orthogonality of Parameters

The probability distribution is denoted as $p(x, \xi)$, where ξ is either θ or η in our case. The Fisher information matrix is defined by the expectation of the product of two score functions,

$$g_{IJ} = E \left[\frac{\partial}{\partial \xi_I} \log p(x, \xi) \frac{\partial}{\partial \xi_J} \log p(x, \xi) \right],$$

where I denotes components of ξ . Two parameters ξ_I and ξ_J are said to be orthogonal when their scores are not correlated,

$$E \left[\frac{\partial}{\partial \xi_I} \log p(x, \xi) \frac{\partial}{\partial \xi_J} \log p(x, \xi) \right] = 0,$$

in other words the (I, J) component G_{IJ} of Fisher information matrix vanishes. It is remarkable that parameter θ_I is orthogonal to parameter η_J for $I \neq J$. When ξ_I and ξ_J are orthogonal, changes $d\xi_I$ and $d\xi_J$ are clearly separated, because the respective changes in the score are orthogonal. The orthogonality is useful for characterizing the parameters (Nakahara et al. 2006).

Higher-Order Correlations

Let us consider the set of parameters $\eta^1, \dots, \eta^k$ consisting of the joint firing probabilities up to order k . Then, they are orthogonal to the natural parameters $\theta^{k+1}, \dots, \theta^n$ of which orders are higher than k (Amari 2001). Therefore, θ^2 is a parameter which is orthogonal to the firing rates η^1 . On the other hand, the third-order parameters θ^3 are orthogonal to the firing rates η^1 and joint firing rates η^2 of any pairs of neurons, so that they are not affected by pairwise correlations given by the joint probability of two neurons. Therefore, θ^3 represents higher-order interactions of three neurons.

This shows that θ^2 are responsible to pairwise correlations and θ^3 are responsible for triple-wise correlations which cannot be decomposed into pairwise correlations. Higher-order correlations are determined in this manner (Abeles and Gerstein 1988).

Higher-Order Interactions and Dichotomized Gaussian Distribution

The full model S includes N degrees of freedom which are too large to handle. Tractable models

are required. The Boltzmann machine, sometimes called the maximum entropy family, includes only up to the second-order interactions so that its degrees of freedom is of the order of n^2 . The dichotomized Gaussian distribution is another model, where each neuron collects information from its environment, such that its membrane potential is subject to a Gaussian distribution. Its output is 0 or 1, depending on whether it exceeds a threshold or not. So it is written as

$$x_i = \begin{cases} 1, & u_i > h, \\ 0, & u_i \leq h, \end{cases}$$

where h is the threshold and u_i are membrane potentials of neurons $i = 1, \dots, n$ which together are subject to a joint Gaussian distribution (Amari et al. 2003). The degrees of freedom of this model are order of n^2 so that the model is tractable. It is possible to fit experimental data by using the dichotomized Gaussian model (Macke et al. 2011; Yu et al. 2011). It is interesting to see dichotomization generates higher-order correlations even when there are none in a continuous random variable.

Temporal Structure of Spikes

Temporal structure of spikes is studied by using various temporal models such as the Markov model. A renewal model is often used to represent temporal structure. Let T be an interspike interval of spikes of a neuron. The renewal model assumes that a sequence $T_1, \dots, T_k$ of intervals is independently distributed. The gamma distribution is a frequently used model which has the following probability density of T :

$$p(T; \kappa, \xi) = \frac{(\xi\kappa)^\kappa}{\Gamma(\kappa)} \Gamma^{\kappa-1} \exp\{-\xi\kappa T\}.$$

It includes two parameters ξ and κ . ξ is the parameter representing the firing rate of a neuron and κ is responsible for the refractoriness after spike. It is called the shape parameter.

When both ξ and κ are constant, it is easy to estimate them from observed data. However, the

firing rate ξ usually changes over time, while the shape parameter κ is considered to be fixed. In such a case, one needs to estimate κ under the condition that ξ changes. This is a semiparametric statistical problem since the values of ξ at each interval are unknown. Information geometry is applicable in such a case too (Miura et al. 2006).

Let us assume that the values of ξ are the same at least for two consecutive intervals T_{2i} and T_{2i+1} . Then, the estimating equation of κ is given by

$$\sum_i [\log T_{2i} T_{2i+1} - 2 \log (T_{2i} + T_{2i+1}) + 2\phi(2\kappa) - 2\phi(\kappa) = 0],$$

where $\phi(\kappa)$ is the bi-gamma function. The statistics which is used for estimation is

$$S_I = \frac{1}{2} \sum_j \log \frac{4T_{2i}T_{2i+1}}{(T_{2i} + T_{2i+1})^2}.$$

This is related to Shinomoto's L_V (Shinomoto et al. 2003).

Information Measures of Redundancy and Synergy in Neural Activity

Michael C. Gastpar
University of California, Berkeley, CA, USA
Ecole Polytechnique Fédérale de Lausanne (EPFL), EPFL-IC-ISC-LINX, BC 106, Lausanne, Switzerland

Definition

Two descriptions of an underlying signal should be expected to be more informative than either one of the descriptions itself. However, several scenarios can be imagined. First, if the two descriptions each represent independent aspects of the underlying signal, then the two descriptions should be twice as informative as any one by itself. Second, if the two descriptions provide partially overlapping information, then the two descriptions together should be *less than* twice as informative as any one by itself. In this case, we say that the two descriptions are *redundant*. A third scenario requires a somewhat more specific setup. Namely, suppose now that each description provides a *noisy* version of the underlying signal, but with different noises. Then, it could happen that the two noises cancel each other out and, hence, that the two descriptions together are *much more* than twice as informative as any one by itself. A similar observation applies if the noises only approximately cancel each other out. In these cases, we say that the two descriptions are *synergistic*.

The next goal is to *quantify* the degree of redundancy or synergy present in a collection of signal descriptions. Many different approaches to this can be envisioned. The present note reviews the use of information measures for this purpose.

Detailed Description

Information Measures of Redundancy and Synergy

Redundancy and synergy can be quantified in many different ways. The present note concerns *information measures*, as pioneered by Shannon (1948).

Based on an intuitive understanding of Shannon's information measure, it is natural to propose the following information measure of synergy and redundancy of two neurons, neuron A and neuron B:

$$R = I_A + I_B - I_{AB} \quad (1)$$

Here, I_A is the information provided by the response of neuron A alone, I_B is the information provided by the response of neuron B alone, and I_{AB} is the information provided by both responses together. This measure appears in many sources, including Rieke et al. (1996, p. 268). We then have the following terminology:

1. If $R = 0$, the two neurons respond *independent* of each other.
2. If $R > 0$, the two neurons are said to respond in a *redundant* fashion.
3. If $R < 0$, the two neurons are said to respond in a *synergistic* fashion.

It is easy to see that R cannot be larger than $I_A + I_B$. However, a sometimes undesirable feature of this definition is that R can be arbitrarily negative irrespective of the values of I_A and I_B . To see this, it is sufficient to consider a scalar normal (Gaussian) probabilistic model. Supposing that the underlying signal has unit variance and that the responses are simply noisy versions of this signal, where the noises have unit variance and correlation coefficient ρ , we find $R = (1/2)/\log_2(4(1 + \rho)/(3 + \rho))$. As should be expected, this is maximized when $\rho = 1$, the case where the two noises are exactly equal, representing the case of maximal redundancy. However, as ρ approaches -1 , it becomes arbitrarily negative, representing the case of maximal synergy.

The literature introduces many slight variants of this quantity, particularly introducing normalization. For example, in Reich et al. (2001), Machens et al. (2001), a “redundancy index” is introduced which can be expressed as $R/\min\{I_A, I_B\}$ (where we note that Machens et al. (2001) incorporates a Gaussian probabilistic assumption into the definition). Another popular normalization is to define $r = R/I_{AB}$ as this quantity is now bounded between -1 and 1 ; see, e.g., Schneidman et al. (2003).

Finally, it should be clear that the above redundancy measure R is easily extended to many neurons: In general, it is simply the difference between the sum of the individual informations and the joint information (leveraging all neurons simultaneously for decoding).

Should We Expect Redundancy and Synergy in the Neural Code?

Let us first consider the scenario where we get to design the representation (the code) completely freely. For this scenario, Shannon has shown that when optimally representing or compressing information, the resulting descriptions will be independent of each other; hence, there will be neither redundancy nor synergy. There are two fundamental assumptions underlying his proof. First, the descriptions are deterministic functions of the underlying information. Second, the descriptions are available in full at the destination.

There appears to be a wide consensus that both of these assumptions are violated in neural systems. In particular, successive runs of the same experiment reveal variations in the descriptions, suggesting that the code is not a deterministic mapping. Moreover, there is also experimental evidence that descriptions are merged, altered, or lost in transit as they advance in the neural processing pathway. Therefore, the optimal representations need not be independent. Rather, they may be redundant or synergistic. Shannon’s information theory has not yet been fully extended to cover such scenarios, revealing only partial results to date. Therefore, contemporary information theory cannot make a clear prediction concerning the optimal degrees of redundancy or synergy in a network.

Some Experimental Studies of Redundancy and Synergy via Information Measures

Many experimental studies have identified synergy and redundancy via information measures in various parts of the neural system. We briefly discuss a few here. The beginning appears to be marked by the studies presented in Reich et al. (2001), Machens et al. (2001), Nirenberg et al. (2001), which all concern sensory modalities. To take them up in turn, in Reich et al. (2001), the authors consider the primary visual cortex in monkeys and report results on the relationship between the redundancy and the size of the considered cluster of neurons. In Machens et al. (2001), the authors consider the insect auditory pathway. They analyze the redundancy conditioned on stimulus classes and, among other findings, observe that stimuli with higher bandwidth lead to reduced redundancy. Finally, in Nirenberg et al. (2001), the authors study the importance of correlated firing in retinal ganglion cells in the mouse. They use a redundancy measure similar to R as defined above to conjecture that correlations are not important and that the cells act mostly independently.

Redundancy and synergy have also been studied in motor cortex via information measures. In Narayanan et al. (2005), the authors report widespread redundant neuron populations in the rat motor cortex. In So et al. (2012), a similar consideration is applied to the monkey motor cortex, both in natural and prosthetic motor control.

Another use of redundancy was presented in Amin et al. (2013), concerning the auditory cortex. The study compares songbirds raised in a white noise environment to controls and finds an increased redundancy in the former when natural stimuli are applied.

Computational Issues

While it is often possible to empirically assess information measures for a single neuron from usual data sets, it is much more challenging to estimate the joint information for a population of neurons. The data requirements increase

exponentially with the size of the population. To deal with this issue, a standard approach involves statistical modeling assumptions. For example, in Machens et al. (2001), the authors consider Gaussian statistical models, such that information estimates only depend on second-order statistics that can be estimated reliably from usual data sets.

Information Processing in the Olfactory Bulb

Angelo Pirozzi¹ and Enrica Pirozzi²

Definition

The information processing in the olfactory bulb refers to the ensemble of concurrent dynamics of

chemical and electrical type triggered by the interaction of odors (the information) with the olfactory mucosa and then acting to stimulate the olfactory bulb by which the encoded information arrives to the brain.

Detailed Description

The olfactory system is the pathway by which the odors (mixture of different chemical molecules, the odorants) are perceived, i.e., it performs the information processing. The key role of such a process is played by the *mitral cell*: it is the main component of the olfactory bulb. After the stimulations received from the *olfactory sensory neurons*, the mitral cell conveys the information in order to transmit it to the cerebral cortex (Linster 2014).

Referring to Kavoi and Jameela (2011), Squire et al. (2012), and Kandel et al. (2013), we describe the process from the beginning. Indeed, the information processing starts in the *olfactory epithelium* where it is possible to distinguish several types of cells among them the olfactory sensory neurons. They are small neurons provided with a long dendrite which protrudes into the mucus covering the nasal cavity. At this level, the dendrite gives rise to numerous extensions called *cilia*. These elements have receptors on their surface specialized to bind odorants by means of an hydrogen bond.

It is estimated that the human being is able to detect about 10^4 odorants, but the average number of receptors is only 350 (about). Each odorant molecule interacts with more than one type of receptor. This means that molecules of the same odorant bind a specific sequence of receptors. The surface of the olfactory neurons is provided of only one type of receptor; therefore, the coupling interaction between odorant molecules and receptors originates the activation of a set of neurons. This can be viewed as a *combinatorial code* realizing the perfect match between an odorant and a particular pattern of activated neurons. In this way, the large number of different odors can be detected by the olfactory bulb even if the number of receptors is clearly lower: indeed, each odor is encoded by means of the combinatorial code deriving from

which and how much olfactory receptors are activated during the above interaction.

The odorants' binding causes variations in the membrane potential of olfactory neurons until it attains the threshold value needed to open voltage-dependent sodium channels. This event originates the *firing* of the olfactory neuron as an action potential transmitted by means of its axon. This phenomenon is known as the *sensory response* and it is subject to the *adaptation phenomenon*; the latter can be identified as the decline of the firing rate during such response. The adaptation is essentially due to the action of calcium which activates proteins triggering a cascade of chemical reactions.

The axons of the olfactory neurons terminate on the dendrites of olfactory bulb neurons within reticular structures called *glomeruli*. Each axon terminates in only one glomerulus where it establishes a synapse with the dendrite of typical bulbar cells: the so-called *mitral cells* (Li 2013).

In each glomerulus, the axons of several thousand sensory olfactory neurons converge on the dendrites of approximately 40–50 bulbar neurons. In the glomerulus occurs the transmission of the information between the olfactory sensory neurons and the mitral cell (Migliore and McTavish 2013). This is the basis of a convergence process aimed to convey the sensory information to limited and well-defined areas of the ipsilateral cerebral hemisphere. However, the organization of sensory information is different from that of the epithelium. Although olfactory sensory neurons with the same odorant receptor are randomly scattered in one epithelial zone, their axons converge in the same glomerulus.

Each glomerulus, and each mitral neuron connected to it, receives input from just one type of sensory neuron. This organization has the advantage to maintain the arrangement of inputs in the olfactory bulb unaltered. The result is a precise arrangement of inputs from different odorant receptors. Because each odorant is recognized by a unique combination of receptors, each odorant also activates a unique combination of glomeruli in the olfactory bulb. In summary, we can say that the combinatorial scheme based on activated receptors is refined at the level of glomeruli, while retaining the information it carries.

Each glomerulus is also encircled by *periglomerular interneurons*: they receive excitatory inputs from sensory axons and make inhibitory dendro-dendritic synapses with mitral cell dendrites in that glomerulus. The periglomerular cells are considered to have a role in *signal modulation*. In the processing of stimuli, the mitral cells make an active synapse with inhibitory interneurons called *granule cells*. This connection constitutes a negative feedback in order to turn off the mitral cell itself.

Finally, the axons of the mitral cells project to the olfactory cortex. The olfactory cortex is defined as the portion of the cortex that receives the direct stimulus from the olfactory bulb and comprises five areas: the anterior olfactory nucleus, the anterior and posterior cortical nuclei of the amygdala, the olfactory tubercle, part of the entorhinal cortex, and the piriform cortex (the largest olfactory cortical area).

At the end, we can remark that the olfactory bulb plays its role as an information processor placing itself in the middle between the odor sensation and the odor perception. The sensation is the capacity to bring the information from the outside world to the nervous structures where they are analyzed, codified, and integrated with stimuli of different sensory areas (those related to the vision, the memory, the emotions) (Linster and Cleland 2014). The perception is the capacity to become aware of the information brought by the stimulus as a result of the complex elaboration made during the sensation process.

On Mathematical Modeling of Information Processing

For modeling purposes, in the previous description, we can distinguish three essential steps responsible of the information processing: (1) the impact of the odors on the olfactory mucosa, i.e., the binding of the odorant molecules in the cilia of the olfactory sensory neurons and the consequent electro-chemical reactions, (2) the interaction between the olfactory sensory neurons and the mitral cells by means of the reticular structure of glomeruli, and (3) the propagation of the stimulus from the mitral cells to the cortex. During the step (1), all concurrent dynamics produce a combinatorial code of the information

received from the outside; the code is based on the number and on the type of the activated receptors. In the step (2), taking into account the previous combinatorial code, a firing activity of specified olfactory sensory neurons occurs in the glomeruli and finally, in the step (3), the mitral cells stimulated by means of the glomeruli provide to propagate the stimulus until to the cortex.

It appears therefore evident that the incoming information is appropriately transformed, at first, into a combinatorial code which decides which and how many neurons must be involved in the information transmission, and subsequently their firing activities provide to bring the information at the level of perception. Definitively, the information processing can be viewed as a transformation in *space* (the geometry of the network and of the connections of the activated neurons) and in *time* (rate and timing of firing activities) of the input information.

Remarking that the process is still the subject of extensive studies, a very large number of papers is dedicated to mathematical models for the description, the comprehension, and the prediction of specific aspects of this complex neuronal dynamics, among them those of stochastic type (see, for instance, Burkitt (2006), Levakova et al. (2015), and reference therein). These models are characterized by the use of the *noise* to model the random fluctuations converting some additional unknown dynamics that can affect the main process. Stochastic models of networks of interacting neurons (Buonocore et al. 2014; Carfora and Pirozzi 2017) can be well adapted to represent the physical geometry of the olfactory system, its connections, and the activation scheme. Furthermore, specific models are devoted to the investigation of the neuronal code deriving from the timing and the rate of the firing activity (Buonocore et al. 2015; Shinomoto 2014; D'Onofrio and Pirozzi 2016) of all involved neurons. Moreover, the modeling of some other collateral, but not less important, phenomena also has been considered in order to improve the knowledge of this topic: the adaptation phenomenon (Buonocore et al. 2016), the feedback actions (Vidybida and Shchur 2018), multitimescale dynamics (Kobayashi et al. 2009), some other

actions that can be also represented as a sort of neuronal memory (Hodara and Löcherbach 2017; Pirozzi 2017; Abundo and Pirozzi 2018; Ascione and Pirozzi 2018), or effects of different noises in the models (D'Onofrio et al. 2018). Specific measures of information have also to be considered (see, for instance, Kostal and Shinomoto (2016), Kostal and D'Onofrio (2018), and references therein). Finally, specialized techniques of the parameters' estimation (Vich et al. 2017) reveal powerful tools to verify how well some of the above mathematical models adapt to the phenomenological evidences.

Insect Olfaction: A Model System for Neural Circuit Modeling

Nitin Gupta and Mark Stopfer
National Institutes of Health, NICHD, Bethesda, MD, USA

Definition

Insect olfactory system denotes the network of cells – including the sensory neurons located on the antennae and the interneurons located in several areas of the brain such as the antennal lobe, the mushroom body, and the lateral horn – that work together to enable the sense of smell in an insect. Here we describe this circuit and consider why it makes a good model system for computational modeling of neural circuits.

Detailed Description

Olfaction presents some difficult problems. Unlike the visual or the auditory system, whose stimuli – light or sound – can be described along the dimensions of frequency and intensity, the olfactory system works with volatile chemicals, which come in numerous shapes and sizes, defying easy description in one or a few dimensions. But, like visual and auditory stimuli, olfactory stimuli may also vary in their intensity, timing, or spatial distribution. It remains a puzzle how the brain makes sense of this multidimensional input (Laurent 2002).

Many animals, including large mammals and small insects, use odors as cues for finding food and mates or for avoiding predators. Although insects have small brains – with five orders of magnitude fewer neurons than humans – they

possess well-developed olfactory systems comparable in organization and capability to their human counterpart (Hildebrand and Shepherd 1997; Kay and Stopfer 2006). These structural and functional similarities, together with their greater amenability to experimental manipulation, make insects attractive models for studying olfaction. Ongoing experiments in several insect species including locusts, moths, flies, bees, and cockroaches are revealing not only the number, morphology, and responses of olfactory neurons but also their interactions and organization into circuits throughout the brain (Hansson 1999). For the computational neuroscientist interested in modeling neural circuits, the insect olfactory system thus provides a rare combination of simplicity of organization, richness of features, and availability of experimental data, which together allow for biologically plausible and functionally useful models. Below, we illustrate how different types of computational models have drawn upon these advantages of the insect olfactory system to further our understanding of the brain.

Insect Olfactory Anatomy and Physiology

In insects, odor detection begins when odorant molecules in the environment bind to olfactory receptor neurons (ORNs) located on the antennae and other body parts. Different odorants can elicit different patterns of spiking in different but overlapping sets of ORNs. ORNs send their axons to antennal lobes in the brain (Fig. 1), where the axons synapse onto local neurons (LNs) and projection neurons (PNs) within interacting spherical neuropils called glomeruli. In locusts, tens of thousands of ORNs converge onto an estimated 300 LNs and 830 PNs. Local interactions among ORNs (excitatory), PNs (mostly excitatory), and LNs (inhibitory or excitatory) in the antennal lobe cause PN spikes to be synchronized into a fast, ~20 Hz oscillatory rhythm riding atop slower temporal patterns of spikes distributed spatially among the population of PNs. These spatiotemporal patterns encode information about odor

identity, intensity, and timing (Stopfer et al. 2003; Brown et al. 2005).

PNs convey this spatiotemporal code directly to higher olfactory centers of the brain: the mushroom body and the lateral horn (Fig. 1). In the mushroom body, PNs synapse with a large population of Kenyon cells (KCs, 50,000 in locusts). Unlike PNs, each KC responds sparsely to very few odors, with very few spikes (Perez-Orive et al. 2002). KCs send their axons to lobes of the mushroom body, converging upon a small number of neurons, some of which provide feedback to KCs, while others send their output beyond the borders of the mushroom body. In the lateral horn, PNs converge on a diverse population of neurons, all of which respond broadly to odors, and which may extract specific stimulus features such as odor intensity (Gupta and Stopfer 2012). Where information goes after the mushroom body lobe neurons and the lateral horn neurons is not completely clear. This mystery underlies an area of active research.

Computational Models in Insect Olfaction

Many types of computational models exist, and based on their primary purpose, models of the insect olfactory system may be divided into three categories: (a) feature-replication models, which try to reproduce an experimentally observed result to help understand the underlying mechanisms; (b) feature-prediction models, which extrapolate from what has been observed to predict unexplored aspects of neural circuits that can be tested later by experiments; and (c) role-detection models, which help explore the functions of experimentally observed features of neural circuits. Below we illustrate each of these categories with an example, focusing on how the model was constrained by experimental data to be biologically realistic and on what we could learn from the model about the functioning of neural circuits. We note that these three categories are not mutually exclusive; in many cases an individual model may serve multiple purposes, as we illustrate with our fourth example.

Insect Olfaction: A Model System for Neural Circuit Modeling, Fig. 1 Insect olfactory anatomy. Multiple types of olfactory receptor neurons (illustrated here with *multiple colors*) located on antennae sense odors and send their output to local neurons (LNs) and projection neurons (PNs) in the antennal lobe. Inhibitory and excitatory interactions between ORNs, LNs, and PNs help transform the sensory information into a spatiotemporal code, which is then carried by PNs to the mushroom body and the lateral

horn. In the mushroom body, the information is received by a large population of sparsely responding Kenyon cells, which then converge on the mushroom body lobe neurons. In locusts, one of the lobe neurons, the giant GABAergic neuron (GGN), helps maintain sparse responses in KCs by forming a normalizing feedback loop; other insects have similar feedback mechanisms. The targets of other lobe neurons and the lateral horns neurons are still being discovered

Models for Feature-Replication: Origin of Temporal Patterns in PNs

In PNs, the spatiotemporal codes for odors consist of elaborate cell- and odor-specific, reliable patterns of spikes, with periods of high activity interleaving periods of silence. These patterns were thought to be generated entirely by circuit interactions within the antennal lobe when provided excitation from the periphery (Wehr and Laurent 1999). However, recent experiments

showed that stimulating antennae with constant current pulses failed to generate patterns as complex as those evoked by odors (Raman et al. 2010). Further, recordings from ORNs – which provide input to PNs – revealed a diversity of temporal spiking patterns (Hallem and Carlson 2006; Raman et al. 2010). Together, these experiments suggested the patterns of spikes in ORNs may also contribute to the patterns of spikes in PNs.

To assess the relative contributions of ORNs and the antennal lobe circuit in generating the temporal patterns of PNs, Raman et al. (2010) constructed a model. The odor-elicited spiking patterns of ORNs were modeled by five parameters: amplitude, latency, rise and fall time constants, adaptation rate, and baseline firing rate; these parameters were initially set to reflect activity recorded *in vivo* and were constrained so that the combined responses of the model's ORNs matched experimentally recorded electro-antennograms, which reflect the summed activity of the antenna's receptors. The antennal lobe was represented in the model by a network of PNs and LNs, whose relative numbers, connection probabilities, and firing properties were drawn from experiments performed *in vivo*. Set in motion, the model's PNs produced realistic and complex temporal patterns when the ORNs provided realistic, temporally heterogeneous input to the antennal lobe. But, when input from the model's ORNs was reprogrammed to lack normal temporal variety, the PNs produced only simple and unrealistic responses. These results suggest that the temporal patterns of ORNs are required to drive the more elaborate temporal patterns in PNs. The model further revealed that interactions between LNs and PNs in the antennal lobe contribute to the fine-tuning of PN patterning, making the responses of different PNs to an odor more distinct over time, and synchronizing the responsive PNs into an oscillatory rhythm (Raman et al. 2010). These features may be a useful downstream for decoding the output of the PN population (Laurent 2002).

Models for Feature-Prediction

Non-synaptic Inhibition in Olfactory Sensilla

In insects and in other types of animals, ORNs reside in small, hair-like formations known as sensilla. Each sensillum encapsulates a small number of ORNs, whose dendrites bathe in a common pool of sensillar lymph and whose somata soak in a common pool of hemolymph. The potential difference between the sensillar lymph and the hemolymph drives odor-evoked

transduction in ORNs. To examine the possible consequences of housing multiple ORNs together in a sensillum, Vermeulen and Rospars (2004) created a two-part model. The first part comprised kinetic equations to analyze the binding of odor molecules and the resulting conductance changes in ORNs. The effects of these conductance changes were then analyzed in the second part of the model, represented as an electrical circuit and constrained by parameters obtained from electrophysiological recordings from sensillae (Vermeulen and Rospars 2001). This model predicted that direct electrical interactions should occur between two neighboring ORNs and that the coupling should be most effective when the ORNs maximally differ in their chemical sensitivity to an odor; such coupling would cause the presentation of the odor to produce enhanced responses in the sensitive ORN while inhibiting the insensitive ORN.

To experimentally test the possibility of non-synaptic electrical coupling between two neighboring ORNs predicted by the model, one needs to know whether a stimulating odor binds to only one ORN or to both. For technical reasons, this experiment proved difficult until recently when Su et al. (2012) used *Drosophila* genetics to do the trick. Analyzing the ab3 sensillum, which houses two neurons (A and B), Su et al. found that activating neuron A with a brief pulse of odor reduced the ongoing firing of neighboring neuron B. But when neuron A was genetically ablated, the same brief pulse of odor induced no change in neuron B, indicating that the odor affected neuron B indirectly, via neuron A. With further experiments examining synaptic connectivity and behavioral performance, the authors established that interactions between neighboring ORNs represent a form of electrical, non-synaptic lateral inhibition and that these interactions can affect behavior (Su et al. 2012).

Models for Role Detection

Maintaining Sparseness by Inhibitory Feedback

One of the neurons postsynaptic to KCs in the mushroom body lobes of locusts is the giant

GABAergic neuron (GGN). This huge cell, which is analogous to the APL neuron in *Drosophila* and to groups of recurrent neurons in other insects, receives excitatory input in the mushroom body lobe from all KCs and reflects it back as inhibitory output to KCs in the mushroom body calyx (Fig. 1), thus forming a closed negative feedback loop (Papadopoulou et al. 2011). What role does this feedback play? The odor-elicited responses of KCs are reliable and extremely sparse. Using two computational models, Papadopoulou et al. (2011) examined the role of feedback in the sparsening of KC responses. First, using a minimal, time-discrete model comprised of binary neurons, with experimentally derived population sizes and connection probabilities, Papadopoulou et al. (2011) found that high firing thresholds for KCs, in the absence of GGN feedback, could generate responses that were sparse on average, but not reliably across the entire population. Adding the GGN allowed reliably sparse responses, similar to those observed experimentally (Perez-Orive et al. 2002). Second, to take into account the fast synaptic transmission from the GGN to KCs, Papadopoulou et al. built a conductance-based model with Hodgkin-Huxley neurons, containing a tenth as many neurons as found *in vivo*, but organized with the same ratio of PNs to KCs and with the same connection probabilities as observed experimentally. This model, too, generated large fluctuations in KC responses without the GGN but reliably sparse responses with the GGN.

Until the discovery of the KC-GGN-KC feedback loop, a putative feedforward inhibitory pathway from PNs to KCs via the lateral horn was thought to underlie the sparse responses of KCs (Perez-Orive et al. 2002). A close examination of lateral horn neurons, however, found no evidence for the existence of this feedforward inhibitory pathway (Gupta and Stopfer 2012). By rigorously assembling a variety of new experimental findings, the computational models by Papadopoulou et al. explained the role of the GGN and demonstrated that a single inhibitory feedback neuron is sufficient to maintain sparseness in a large population of neurons.

Models that Serve Multiple Functions

Fast Learning in the Antennal Lobe

Sinuous odor plumes and flicking antennae conspire to provide odors to ORNs in discrete, recurring splashes rather than in smooth and constant streams. Recordings from the locust brain show that the responses of olfactory neurons change over the course of such multiple, repeated stimulus presentations: PNs come to produce fewer spikes, but these spikes tend to become more synchronized with spikes in other PNs, resulting in stronger network oscillations (Stopfer and Laurent 1999). These changes appear within a few odor presentations separated by seconds, but last for minutes, and occur independently of receptor adaptation within the antenna. They reflect a fast, short-term form of learning in the antennal lobe.

What mechanisms underlie this fast learning? Bazhenov et al. (2005) modeled the antennal lobe as a network of Hodgkin-Huxley LNs and PNs, whose relative numbers and conductances were based on available experimental data. Input from ORNs to LNs and PNs was modeled by randomly distributed spikes, constrained to generate experiment-matched membrane potential fluctuations in PNs. When activity-dependent facilitation of inhibitory synapses was added to the model's antennal lobe, it reproduced fast learning with dynamics similar to those observed in the experiments.

The success of the model was contingent upon, and thus predicted, the existence of activity-dependent plasticity at inhibitory synapses in the antennal lobe. This prediction is validated by recent results showing facilitation of specific GABAergic synapses after odor exposure in *Drosophila* (Das et al. 2011; Sudhakaran et al. 2012).

What functional role may be served by such fast learning? By manipulating the presence and extent of plasticity in the model, Bazhenov et al. (2005) identified one possible role. Noisy ORN input caused large trial-to-trial variability in the PN spike patterns in the absence of plasticity; this variability was reduced significantly when plasticity was returned to the model. These results suggest

fast learning in the antennal lobe makes olfactory responses more robust to stimulus variability, potentially enabling the animal to better recognize odors in its naturally noisy environment.

Summary

A model is a well-specified description of a complex, sometimes only partially explored system, and, as such, is expected to set aside some biological details. But should the modeler stray too far from what is known, the model may begin to lose its relevance. We assert that the utility of the computational models sampled above – in revealing the mechanisms underlying temporal patterning or fast learning, in predicting non-synaptic inhibitory coupling or activity-dependent facilitation of inhibitory synapses, and in determining the role of feedback inhibition or that of fast learning – is explained in part by a shared motif: they all were tightly constrained by available experimental data. They are just a few of the many useful models in insect olfaction, illustrating how this system, supported by a long tradition of anatomical and physiological exploration (Kenyon 1896), provides a rich platform for modeling neural circuits. These models have begun to reveal the principles of neural computation and their significance for perception, memory, and behavior (Laurent 2002; Gupta and Stopfer 2011). But there is still a long way to go before we can claim to understand olfaction, or the brain.

Exponential integrate and fire model; Izhikevich model; Leaky integrate and fire model; Quadratic integrate and fire model

Definition

The integrate-and-fire (IF) model is a single-compartment model describing the subthreshold dynamics of the neuron membrane potential V . The spiking dynamics is marked by a spiking threshold, potential at which the neuron emits a spike. After spike emission, V is set at the neuron's reset potential. Subthreshold dynamics was initially designed to capture neuron's passive membrane properties, and its dynamics was given by a single first-order linear differential equation.

Variations around this model have been introduced to describe either spike-activated currents, more complex subthreshold dynamics, or more realistic spike initiation dynamics. These models can be two or three dimensional or include nonlinear terms. However, they are always designed to describe the relevant mechanisms with a minimal set of variables and parameters which make them suitable for large-scale simulations or detailed mathematical analysis.

Detailed Description

Leaky Integrate-and-Fire Model

The leaky integrate-and-fire (LIF) model was first introduced by Lapicque (1907) to describe mathematically neuron firing times. It is based on the idea that neuron activity can be captured by the

dynamics of its membrane potential which evolves according to neuron inputs (synaptic or current injection) and passive membrane properties (see, e.g., Eccles 1957). The main hypothesis of the LIF model is that action potential threshold and shape are invariant from spike to spike, and thus a precise description of the spike can be omitted and simply sketched by a spiking threshold. When V reaches this threshold, a spike is emitted, after which V is set at the neuron's resting membrane potential. This simple spiking dynamics captures the nonlinear input–output relationship of neurons and has been the subject of detailed mathematical analysis (Knight 1972; Tuckwell 1988).

Below spiking threshold, the membrane potential dynamics is described by the membrane passive dynamics. The equivalent electrical circuit is sketched in Fig. 1a and its main parameters are the following:

- C_m : the membrane capacitance
- g_L : the leak conductance (or equivalently its membrane resistance $R_m = 1/g_L$)
- E_L : the resting membrane potential, which is the neuron membrane potential in the absence of external stimulation

The standard equation describing the LIF model below threshold is then given by

$$C_m \frac{dV}{dt} = -g_L(V - E_L) + I(t) \quad (1)$$

where $I(t)$ represents any external input (electrode, synaptic, etc.) to the neuron. Another common form of Eq. 1 is

$$\tau_m \frac{dV}{dt} = -(V - E_L) + R_m I(t) \quad (2)$$

where τ_m is the membrane time constant:

$$\tau_m = \frac{C_m}{g_L} = R_m C_m \quad (3)$$

The first term on the right-hand side in Eqs. 1 or 2 is called the leak current. It pulls V toward its resting membrane potential. With this term, the LIF model is the original leaky integrate-and-fire

Integrate and Fire Models, Deterministic, Fig. 1 Basis of the leaky integrate-and-fire (LIF) model. (a) Electrical RC circuit equivalent to the LIF model. (b)

Subthreshold (dashed line) and suprathreshold (full line) activation of a LIF model. LIF parameters: $E_L = -65$ mV, $\tau_m = 10$ ms, $V_r = -70$ mV, $V_{th} = -50$ mV

model (also called forgetful IF). This term is sometimes neglected in which case the model is a perfect integrator (simple integrate-and-fire model, SIF). The previous equations only describe the subthreshold membrane potential dynamics. To capture neuron spiking mechanisms, the LIF model is completed by a constant spiking threshold V_{th} , potential at which the LIF model is considered to have emitted a spike. There is no detailed description of the actual spike shape. Following a spike, the potential V is reset to a reset potential V_r . See Fig. 1b for an example of LIF membrane potential trace.

To take into account the finite width of real spikes and the neuron absolute refractory period, we can add to the LIF model a refractory period τ_{ref} . It is a period following each spike during which the model is insensitive to external inputs. At the end of this period, V is reset at V_r .

Thanks to the simple form of its equation, assuming a constant input current $I(t) = I$, the LIF model trace can be exactly computed between spikes:

$$V(t) = V_r + (R_m I + E_L - V_r) \left(1 - e^{-\frac{t}{\tau_d}}\right) \quad (4)$$

This shows that if the input current is large enough, $R_m I \geq V_{th} - E_L$, then the LIF model emits a spike after a time T such that

$$V_{th} = V_r + (R_m I + E_L - V_r) \left(1 - e^{-\frac{T}{\tau_d}}\right) \quad (5)$$

Finally we obtain the LIF f-I curve, given by

$$f(I) = \frac{1}{\tau_{ref} + \tau_{td} \ln \left(\frac{R_m I + E_L - V_r}{R_m I + E_L - V_{th}} \right)} \quad (6)$$

Note that the logarithmic shape of the f-I curve, close to rheobase (current threshold), is not typical of f-I curves found with more detailed neuron model. Besides, this simple calculation in presence of a constant external input should not mask the strong nonlinearity introduced in the model by its hard spiking threshold making analytical computations more difficult as soon as more complex dynamics are considered. However, the simplicity of the LIF model makes it useful in large-scale simulations of neuronal networks.

Extensions of the LIF Model

The LIF model captures only subthreshold dynamics governed by passive membrane dynamics and has an oversimplified spiking mechanisms which can sometimes generate rather

unphysiological behavior. Thus, many extensions of the model have been proposed to allow a description of additional features found in real neurons. We will describe here three major classes of extension:

- Currents activated during spiking, like afterhyperpolarization currents leading to spike rate adaptation
- Currents active below threshold which can generate resonant membrane properties
- More realistic spiking mechanisms allowing to better capture fast neuronal dynamics

As we will see, the common basis of all the extensions proposed for the LIF model is that they were intended to use the smallest number of parameters and the simplest equation possible to capture additional neuronal dynamics. The model proposed by Izhikevich (2003), gathering many of these extensions, can thus describe most of known neuronal spiking pattern with a very small set of parameters and first-order differential equations. It will be presented at the end of this section.

Spike-Activated Currents

In real neurons, spiking is induced by the strong activation of intrinsic sodium and potassium currents. This leads to a large fluctuation of neuron membrane potential and transient changes of ion intracellular concentration. These effects can cause other voltage-activated or ion-activated (like potassium-dependent) channels to be modulated during spiking. A common example is the activation during a spike of currents leading to spike rate adaptation. These types of currents are transiently activated during a spike but are then slowly inactivated between spikes and tend to hyperpolarize the neuron. The first version of such a current in a LIF model has been introduced by Treves (1993), and its simplest mathematical description is given by

$$\tau_m \frac{dV}{dt} = -(V - E_L) + R_m(-I_a + I(t)) \quad (7)$$

$$\tau_a \frac{dI_a}{dt} = -I_a \quad (8)$$

where the adapting current I_a is incremented by a positive constant r_a at each spike. An example of trace of an adapting LIF model is shown in Fig. 2. Note that the same formalism could be used to describe facilitating currents, leading to afterdepolarization (ADP), by changing to positive sign in front of I_a in Eq. 7. Other versions of the adapting current use a slowly decaying conductance g_a and then define $I_a = g_a(V - E_a)$ where E_a is the reversal potential of the adapting current and has to be lower than V_{th} in order to describe an hyperpolarizing current.

Subthreshold Voltage-Dependent Currents

In the previous section, the spike-activated current (or conductance) was not voltage-dependent between spikes. However, most of real neurons express currents which are activated in a voltage-dependent manner below the spike threshold and affect the neuron dynamics. An accurate description of this type of voltage-dependent currents generally requires to use the Hodgkin-Huxley formalism. However, it is still possible to capture the most salient effects of such currents on the neuron dynamics by restraining their analysis in a narrow voltage band (Izhikevich 2001; Richardson et al. 2003). For example, Richardson et al. (2003) showed that it is possible to linearize the full conductance equation of voltage-dependent conductances around the neuron equilibrium potential to obtain a linear system able to capture membrane potential subthreshold resonance. Adding a standard LIF spiking threshold to the linearized model gives the generalized integrate-and-fire (GIF) model. The standard equation of a GIF model is given by

$$\tau_m \frac{dV}{dt} = -(V - E_L) + R_m(-g_x W_x + I(t)) \quad (9)$$

$$\tau_x \frac{dW_x}{dt} = -W_x + (V - E_x) \quad (10)$$

We emphasize that contrary to the current used to describe spike rate adaptation, here W_x depends on V . Depending on the parameters g_x and τ_x , this allows the system to have fixed points with complex basis solutions like for the simple or damped

Integrate and Fire Models, Deterministic, Fig. 2 Adaptation in a LIF model. *Top*: potential traces of a LIF model with (*full line*) and without (*dashed line*) adaptation current. *Bottom*: buildup of the adaptation

current during spiking. Note that after a transient increase at the beginning of neuron firing, adaptation stabilizes. Adaptation parameters: $\tau_a = 20$ ms, $r_a = 0.2$ nA

harmonic oscillator. Such solutions can capture resonant properties found in real neurons (Hutcheon and Yarom 2000). In Eq. 9 we had only one additional conductance to the original LIF model, but some neuron with low and high resonant frequencies may require two or more currents in order to capture their dynamics. Details on the derivation of additional current parameters from the standard Hodgkin-Huxley equations can be found in Richardson et al. (2003).

Spike Initiation Dynamics

In the standard LIF model, the spiking mechanism is sketched by a constant spiking threshold. However, in real neurons, the action potential is initiated by a strong sodium current with a fast, but not instantaneous, activation. Both mechanisms are similar when we are only interested in slow neuron dynamics, but discrepancies can appear when looking at the response to fast-fluctuating input, for example. Thus, extensions of the LIF model

including a nonlinear term to model the non-instantaneous activation of sodium current have been proposed. The general form of these nonlinear integrate-and-fire (NLIF) models is given by

$$C_m \frac{dV}{dt} = g_L \psi(V) + I(t) \quad (11)$$

where $\psi(V)$ is a function which increases fast enough such that when V grows, it can diverge to infinity in a finite time. In this case, the spike time is given by the time of divergence of V , and it is then reset at potential V_r . It is no longer necessary to choose an arbitrary spike threshold, but for numerical simulation, a spike cutoff has to be defined assuming infinity has been reached.

Using this equation, we can define two important quantities:

- The voltage threshold V_T which is the highest steady-state voltage the neuron can sustain without emitting a spike. If ψ is convex, it is defined by $\psi'(V_T) = 0$.

- The spike shape factor Δ_T which is proportional to the curvature radius of the neuron current–voltage curve at its voltage threshold V_T . It is defined by $\Delta_T = 1/\psi''(V_T)$.

Two major classes of NLIF neurons have been used in the literature. The first one historically is the quadratic integrate-and-fire (QIF) (Ermentrout and Kopell 1986; Ermentrout 1996), also known as the theta model:

$$C_m \frac{dV}{dt} = \frac{g_L}{2\Delta_T} (V - V_T)^2 - I_0 + I(t) \quad (12)$$

For an input current below I_0 , the model exhibits two fixed points: one stable and one unstable. When the input current increases and reaches I_0 , the two fixed points merge and the neuron membrane potential is destabilized through a Hopf bifurcation which is the classical type I dynamics observed in many neuron models.

The second type of well-known NLIF neuron is the exponential integrate-and-fire model (EIF):

$$C_m \frac{dV}{dt} = -g_L(V - V_T) + g_L \Delta_T e^{\frac{V - V_T}{\Delta_T}} + I(t) \quad (13)$$

Here the divergence function is exponential which leads to a spike initiation speed intermediate between the instantaneous LIF spike and the rather slow QIF spike (see Fig. 3a). Fourcaud-Trocmé et al. (2003) have shown that this model captures best the fast dynamics of standard Hodgkin-Huxley-type models for cortical neurons, like the Wang-Buzsáki model (Wang and Buzsáki 1996).

Comprehensive IF Models

The three types of extensions presented previously describe distinct aspects of neuron

Integrate and Fire Models, Deterministic, Fig. 3 Comparison of nonlinear IF models. *Left*: comparison of LIF, QIF, and EIF spiking initiation in response to the same constant current input. We observe that the LIF neuron is very reactive and spikes as soon as it reaches the spiking threshold V_{th} . The EIF model has a smooth but sharp spike, while the QIF model has the slowest spike. *Right*: comparison of LIF, QIF, and EIF f-I curves. We observe that LIF f-I curve has a logarithmic initial portion which is a consequence of its instantaneous spiking

mechanism. QIF and EIF f-I curve initial portion have a square root shape, which depends only on V_T and Δ_T . This shape is classically observed in type I neurons. Parameters: for all models, $C_m = 1$ nF, $g_L = 0.1 \mu S$, $E_L = -65$ mV; **LIF**, *left*, $V_{th} = -60$ mV, $V_r = -70$ mV; **LIF**, *right*, $V_{th} = -63.4$ mV, $V_r = -80$ mV, $\tau_{ref} = 1.35$ ms; **QIF**, $V_T = -59.9$ mV, $\Delta_T = 3.48$ mV, $V_{th} = -30$ mV, $V_r = -62.235$ mV, $I_0 = -0.16$ nA, $\tau_{ref} = 0$ ms; **EIF**, $V_T = -59.9$ mV, $\Delta_T = 3.48$ mV, $V_{th} = -30$ mV, $V_r = -68$ mV, $\tau_{ref} = 1.7$ ms

dynamics but are not exclusive. Some studies proposed to combine them in order to produce simple but realistic neuron models. One of the simplest has been proposed by Izhikevich (2003). It is defined by

$$\frac{dV}{dt} = 0.04V^2 + 5V + 140 - U + I(t) \quad (14)$$

$$\frac{dU}{dt} = a(bV - U) \quad (15)$$

Two additional parameters are the reset $V_r = c$ and the increase d of variable U after each spike. Note that depending on the set of parameters a , b , c , d , it can include all LIF extensions previously described. Using this model, Izhikevich has shown that most of the common recorded discharge patterns could be reproduced (see Fig. 4).

A second comprehensive model is the adaptive integrate-and-fire model (Brette and Gerstner 2005). It is described by

$$C_m \frac{dV}{dt} = -g_L(V - V_T) + g_L \Delta_T e^{\frac{V - V_T}{\Delta_T}} - w + I(t) \quad (16)$$

$$\tau_w \frac{dw}{dt} = a(V - E_L) - w$$

Again, the model must be completed by a reset V_r and the increment b of the adaptive current w at each spike. This model is very similar to the model proposed by Izhikevich (2003) but its subthreshold dynamics and spike initiation dynamics are closer to standard Hodgkin-Huxley models. This facilitates the choice of the model parameters

Integrate and Fire Models, Deterministic, Fig. 4 Example of a comprehensive IF model. The model depicted in the upper equations includes subthreshold dynamics, a spiking mechanisms inspired by the QIF model, and spike-dependent adaptation. All these dynamical aspects depend only on two variables and four

parameters. Careful choices of the parameters can lead to a great variety of neuronal dynamics reminiscent of actual neuronal recordings (Electronic version of the figure and reproduction permissions are freely available at www.izhikevich.com)

based on simple experimental measurements (injection of current pulses, steps, and ramps; see Brette and Gerstner 2005 for details).

Definition

The intermittent control hypothesis proposes that centrally integrated sensorimotor control systems cannot be described by continuous feedback but rather by a sequence of open loop trajectories determined by intermittent feedback (Fig. 1). The times at which feedback occurs, and at which the trajectories are adjusted, can in principle be at regular intervals or determined by events. The latter is termed event-driven control, and events can occur when measured states or predicted state errors exceed a threshold. The purpose

Intermittent Control of Movement and Balance, Fig. 1 Intermittent control. Sensorimotor control of sustained tasks is a process of closed loop feedback in which a controller uses sensory output to control muscle activations which determine movement of the mechanical body. The controller uses sensory analysis (SA) to estimate states and uses a motor system (MS) to generate activations of the muscles. According to the intermittent control hypothesis, a process of refractory response planning

occurs between sensory analysis and the motor system. The refractory response planner uses current states to plan a time-varying trajectory of muscle activations which are executed without feedback. Refractoriness means this control trajectory is not updated until the next trajectory is planned using updated sensory measurements. This refractory response planner is postulated to reside with the basal ganglia and associated motor decision-making regions of the frontal cortex

of intermittent control is to provide time within the feedback loop for computation using current measured states to inform the next iteration of open loop predictive control. By comparison with continuous control, intermittent control gains adaptability at the expense of bandwidth.

For any task, this hypothesis is falsifiable and can be tested using appropriate experiments and the model-based definition of intermittent control. In the particular case of human balance control, muscle forces should follow trajectories which are determined intermittently by feedback of perceived body position, and events could correspond to body sway exceeding a threshold or to predicted sensory states exceeding a threshold.

Detailed Description

As discussed by Gawthrop et al. (2015), intermittent control has a long history in the physiological literature including Craik (1947), Vince (1948),

Navas and Stark (1968), Neilson et al. (1988), Miall et al. (1993), and Bhushan and Shadmehr (1999). There is strong experimental evidence that some human control systems are intermittent (Craik 1947; Vince 1948; Navas and Stark 1968; Bottaro et al. 2005; Loram et al. 2012; van de Kamp et al. 2013b), and it has been suggested that this intermittency arises in the central nervous system (CNS) (van de Kamp et al. 2013a). For this reason, computational models of intermittent control are important, and, as discussed below, a number of versions with various characteristics have appeared in the literature. Intermittent control has also appeared in various forms in the engineering literature including Ronco et al. (1999), Gawthrop and Wang (2009), and Gawthrop et al. (2015).

As shown in Fig. 1, intermittent control action may be initiated at regular intervals determined by a clock or at irregular intervals determined by events; an event is typically triggered by an error signal crossing a threshold. There is evidence that

human control systems are, in fact, event driven (Navas and Stark 1968; Loram et al. 2012; van de Kamp et al. 2013a; Loram et al. 2014). For this reason, this entry focuses on event-driven control.

Computational Model

A detailed computational model of intermittent control is given by Gawthrop et al. (2011) and refined by Gawthrop et al. (2015) to include occluded sensing and multivariable control. This section summarizes the computational model.

The computational model of intermittent control is based on the *underlying continuous-time design method* of Fig. 2; in particular the classical state-space approach is the basis of the intermittent control of Gawthrop et al. (2011). There are two relevant versions of this approach: state feedback and output feedback. State-feedback control requires that the current system state (e.g., angular position and velocity of an inverted pendulum) is available for feedback. In contrast, output feedback requires a measurement of the system output

(e.g., angular position of an inverted pendulum). The classical approach to output feedback in a state-space context is to use an observer (or the optimal version, a Kalman filter) to deduce the state from the system output.

Human control systems are associated with time delays. In engineering terms, it is well-known that a predictor can be used to overcome time delay. As discussed by many authors (Kleinman et al. 1970; Gawthrop et al. 2011; Loram et al. 2012), it is plausible that physiological control systems have built-in model-based prediction. Thus intermittent control is based on an underlying predictive design.

As explained in detail elsewhere Gawthrop et al. (2011, 2015), intermittent control (Fig. 3) adds three components to the underlying design method of Fig. 2:

1. A *Hold* device which produces an open-loop state trajectory $\mathbf{x}_h$ based on the most recent intermittent sample at time t_i

Intermittent Control of Movement and Balance, Fig. 2

The Observer, Predictor, State-feedback (OPF) model. The block labelled “NMS” is a linear model of the neuro-muscular dynamics with input $u(t)$; in the engineering context, this would represent actuator dynamics. “System” is the linear external controlled system driven by the externally observed control signal u_e and disturbance d and with output y and associated measurement noise v_y . The input disturbance v_u is modelled as the output of the block labelled “Dist.” and driven by the external signal

v . The block labelled “Delay” is a pure time delay of Δ which accounts for the various delays in the human controller. The block labelled “Observer” gives an estimate $\mathbf{x}_o$ of the state $\mathbf{x}$ of the composite “NMS” and “System” (and, optionally, the “Dist.”) blocks. The predictor provides an estimate of the future state error $\mathbf{x}_p(t)$ the delayed version of which is multiplied by the feedback gain vector $\mathbf{k}$ (block “State FB”) to give the feedback control signal u . (This figure is based on Gawthrop et al. (2011, Fig. 1) which is in turn based on Kleinman (1969, Fig. 2))

Intermittent Control of Movement and Balance, Fig. 3 Intermittent control. This diagram has blocks in common with those of the OPF of Fig. 2: “NMS”, “Dist.”, “System”, “Observer”, “Predictor,” and “State FB” which have the same function; the continuous-time “Predictor” block of Fig. 2 is replaced by the much simpler intermittent version here. There are three new elements: a sampling

element which samples x_w at discrete times the block labelled “Hold”; the system-matched hold, which provides the continuous-time input to the “State FB” block; and the event detector block labelled “Trig.” which provides the trigger for the sampling times t_i . The dashed lines represent sampled signals defined only at the sample instants t_i . This figure is based on Gawthrop et al. (2011, Fig. 2)

2. A trigger device (“Trig.”) which determines when (t_i) intermittent samples are taken
3. A sampling element (represented by a switch symbol) which samples the observed system state at each time t_i

A computational model of intermittent control based on Fig. 3 is given by Gawthrop et al. (2011, 2015).

Explaining Experiments

A number of simulated examples are given by Gawthrop et al. (2011, 2015) to illustrate how the computational model of intermittent control can explain a number of known phenomena associated with human control systems. But as a scientific hypothesis, the computational model of intermittent control must also be compared with real experimental data.

Identifying Intermittent Models

As discussed by Gawthrop et al. (2011), intermittent control can *masquerade* as continuous

control. For this reason experiments must be specifically designed to reveal intermittency. For example, Loram et al. (2012) use a special paired-step set-point sequence; Gollee et al. (2012, 2017) use a special periodic multi-sine input signal.

Moreover, conventional methods for identifying continuous time systems cannot be used. Loram et al. (2012) introduce a novel time-domain approach, and Gollee et al. (2012) introduce a novel frequency domain approach.

Sway

Human balance has a characteristic sway motion. As discussed by Gawthrop et al. (2014), such sway can be explained by the nonlinear behavior of event-driven intermittent control of an inverted pendulum.

Stick Balancing

Balancing a stick on a fingertip is a fourth order unstable control problem which is challenging to humans and is, therefore, an interesting test-bed for computational models of intermittent control.

Gawthrop et al. (2013) present a cascaded form of intermittent control which explains the perceived continuous nature of the control, while the event-driven properties of intermittent control explain experimentally observed variability.

Motor Noise

Although, in some circumstances, the human operator is described adequately by linear translation of sensory input to motor output, such descriptions have a significant *remnant* when compared to experimental data. This remnant has been attributed to sensorimotor noise.

However, Gollee et al. (2017) have shown that remnant can be attributed to aperiodic sampling associated with event-driven intermittent control.

The Neural Substrate of Intermittent Control

The development of intermittent control in the engineering context was driven by the desire to combine continuous time predictive feedback control with intermittent optimization (Ronco et al. 1999). In essence, the intermittency provides the time required for the optimization. It may be that a similar rationale holds for living control systems (van de Kamp et al. 2013a) where the intermittency provides the time for the refractory response planner of Fig. 1.

In human control, the evidence for intermittent control is behavioral and derives from evidence of the psychological refractory period in relation to discrete tasks (Pashler and Johnston 1998) and from visually guided manual tracking and visually guided whole body tracking tasks (van de Kamp et al. 2013a; van de Kamp et al. 2013b; Loram et al. 2012, 2014; Miall et al. 1986). While a neural substrate has not yet been established, from general knowledge of the anatomy and function of neural regions (Loram et al. 2014), it is a current hypothesis that the basal ganglia, and specifically the subthalamic nucleus (STN), are relevant (Boca et al. 2019), and there is also interest in the link between abnormal intermittent control and Parkinson's disease (Perera et al. 2018). For discrete tasks, there is also fMRI evidence for substrates of refractoriness in the frontal and prefrontal cortex (Dux et al. 2006).

Definition

The intermittent time-delayed feedback control is a model of neural strategy for stabilizing human upright stance. It exploits two types of instability of the human postural control system. One is the

instability of purely mechanical, passive dynamics of the inverted pendulum-like human body in the absence of the active feedback control, due to the fact that intrinsic, i.e., passive, ankle stiffness is insufficient for stabilizing the upright posture, whereby the upright posture is characterized by a saddle-type unstable equilibrium with stable and unstable manifolds. The second is a delay-induced unstable oscillation in the system of the inverted pendulum with an active feedback controller with a large signal transmission delay. In the intermittent control model, the instability is compensated by switching between those two unstable dynamics in an appropriate state-dependent manner, where the switching function is implemented in such a way that the feedback controller is switched off when the state vector is near the stable manifold of the saddle, and it is switched on otherwise.

Detailed Description

Summary of the Intermittent Control Model

The intermittent (time-delayed) feedback is a model of neural motor control strategy for stabilizing human upright stance (Asai et al. 2009; Bottaro et al. 2008; Suzuki et al. 2012). In contrast to the traditional impedance control hypothesis (Maurer and Peterka 2005; Winter et al. 1998), the model assumes that the central nervous system may intermittently *inactivate* the time-delayed active feedback control action, in order to exploit the purely mechanical, passive dynamics of the human body in the absence of the active feedback control. A standing body without active control may be simply modeled by an inverted pendulum, referred to as *the off-system*, whose natural tendency to fall is counteracted but not fully compensated by the passive stiffness of the ankle joint, due to the fact that such stiffness is lower than the growth rate of the gravitational toppling torque (Casadio et al. 2005; Loram and Lakie 2002). Thus, the upright posture of the off-system is a saddle-type unstable equilibrium (*the saddle point*) in the state space. Since the saddle point is accompanied by

stable and unstable manifolds (eigenspaces of stable and unstable eigenmodes) in the state space, the state point can transiently approach the saddle point, if it is near the stable manifold. This would then be followed by a departure from the saddle point along the unstable manifold, determining a fall without feedback intervention (Fig. 1 left panel). In response to an incipient fall, the brain may turn on an active feedback control action, thus switching from the off-system to *the on-system*. Typically, the intermittent control model operates with small feedback gains for the on-system (Asai et al. 2009; Suzuki et al. 2012), namely, gain values that would be incapable to achieve stability even if the feedback controller were persistently activated. Moreover, regardless of the feedback gain values, the persistent feedback control is highly prone to delay-induced instability, leading to a divergent, unstable oscillation around the upright equilibrium point. The rationale of the intermittent control strategy is that the unstable dynamics of the on-system can be exploited, in the sense that the actively driven spiraling out of the state point may provide an opportunity to transverse the stable manifold of the off-system at some time (Fig. 1 right panel): inactivating the active feedback controller at that time (switching from the on-system to the off-system) would trigger another transient behavior approaching the saddle point along or near the stable manifold. In other words, the key feature of the intermittent control model is that, although the off- and on-systems are both unstable, the combination of the two according to the switching mechanism can achieve *bounded stability* (Bottaro et al. 2008) with a limit cycle oscillation that represents a postural sway during quiet stance, even in the absence of motor noise. Another remarkable characteristic of the model is the small joint impedance that originates from the null feedback gains in the off-system and the small feedback gains in the on-system, leading to joint flexibility that induces *power-law-like postural sway* when driven by tiny additive torque noise corresponding to the hemodynamic perturbations during stance (Nomura et al. 2013).

Intermittent Control Strategy for Stabilizing Human Quiet Stance, A Model of the, Fig. 1

The intermittent stabilization strategy of human quiet stance, based on an inverted pendulum model. The left panel illustrates typical dynamics of the pendulum without active feedback control (off-system) in the phase plane (tilt angle θ vs. angular velocity ω), where the upright posture (the origin) is a saddle-type unstable equilibrium point with stable and

unstable manifolds. The right panel illustrates dynamics of the pendulum with time-delayed feedback control (on-system), where the system shows unstable oscillation due to delay-induced instability. Appropriate state-dependent switchings between these two unstable dynamics make the overall dynamics stable, which are characterized by a bounded stability with a limit cycle oscillation

Physiological and Theoretical Background

Human upright posture during quiet stance, as a mechanical system when no active neural control is provided, is unstable due to insufficient passive stiffness of the ankle joint for overcoming the gravitational toppling torque (Casadio et al. 2005; Loram and Lakie 2002). The central nervous system (CNS) stabilizes the upright posture using neural feedback controllers that generate the active control torques in a robust way, by compensating the danger of instability induced by the large neural feedback transmission delay, which is of the order of 200 ms, while maintaining a level of flexibility that induces the standing body to exhibit stochastic fluctuations, referred to as the *postural sway*.

Postural sway is often measured as a stochastic motion of the center of pressure (CoP) acting on the foot soles during stance. A typical CoP motion in healthy adults is about 0.02–0.04 m of amplitude during quiet stance in both anterior-posterior (AP) and medial-lateral (ML) directions, although the sway size is highly individual dependent (Yamamoto et al. 2015). Collins and De Luca showed that temporal patterns of postural sway for healthy adults exhibit power-law-like behaviors (Collins and De Luca 1994). Specifically, for

the short-term/high-frequency regime (about 0.7–10 Hz), increments of the process behave as those of a positively correlated random walk, corresponding to successive micro-falls due to the gravitational drift. For the long-term/low-frequency regime (about 0.01–0.7 Hz), increments of the CoP motion behave as those of a random walk with slightly negative correlation, corresponding to movements approaching the upright posture, which can be characterized by a power-law-like power spectral density (PSD) function of the following form: $f^{-\beta}$ with $\beta \sim 3/2$ as exemplified in Fig. 2a. Those characteristics are altered in patients with neurological diseases, such as Parkinson's disease, that cause motor dysfunctions, including postural instability (Xiang et al. 2018). Typical patterns of alterations have been reported, including a loss of the $f^{-3/2}$ behavior at the low-frequency regime (Yamamoto et al. 2011) (see Fig. 2b). Thus, the major issue on the study of human postural control is to unveil dynamic mechanisms of how the CNS stabilizes the upright posture in a robust manner and, at the same time, how the power-law-like postural sway pattern is generated. Moreover, clinical challenges are to understand how the upright posture is destabilized in neurological patients and how the

Intermittent Control Strategy for Stabilizing Human Quiet Stance, A Model of the, Fig. 2 Typical fluctuation patterns of CoP (center of pressure) during quiet standing in a healthy subject (a) and a patient with Parkinson's disease (b). For each of them, the sway patterns are illustrated by three graphs: (1) a time series of the

anterior-posterior (AP) component of the CoP oscillation; (2) the CoP trajectory in the AP-ML (mediolateral) plane, with 95% confidence ellipse; (3) the power spectral density (PSD) of the AP component of the CoP, with the linear regression line for the low-frequency regime

power-law-like sway pattern is lost in patients with Parkinson's disease.

In the field of neuroscience of motor control, it has been a common view that the brain stabilizes unstable body dynamics using impedance control, which resists destabilizing motion by regulating co-activation (co-contraction) levels of antagonist muscles (Hogan 1984). In such cases, the CNS would stabilize unstable dynamics by learning optimal impedance, in which optimally selected pairs of antagonist muscles associated with the instability are co-activated in a preprogrammed manner (Burdet et al. 2001). On one hand, such feedforward, nonreactive control strategy decreases the risk of delay-induced instability, but on the other, it forces a trade-off between stability and high muscle activation, as well as a similar trade-off between minimizations of task-related errors and energetic costs. That is, increasing impedance enhances the stability and reduces deviations from the desired goal of a motor task, but co-contraction of muscles increases metabolic cost and, at the same time, decreases joint flexibility. In this sense, the impedance control strategy is rather incompatible with the minimum intervention principle, which is a rational

organizing characteristic for many biological systems (Todorov and Jordan 2002). Since upright stance is a basic motor control function of daily life activity, increases in the energy cost could be critical. Thus, it is very likely that the CNS chooses alternative strategies for achieving the upright stance other than the impedance control strategy.

There are multiple strategies alternative to the impedance control. The use of internal models acquired by the CNS, representing the relationships between motor commands and movements, is one of such strategy. It might be capable of acting as a finite-horizon model predictive controller, i.e., as a feedforward controller, to compensate the destabilizing effect of feedback delay as argued for ballistic voluntary movement (Wolpert and Kawato 1998) and also as a possible strategy used for the postural control (Gawthrop et al. 2011; Morasso et al. 1999). Another way to resolve the trade-off might be to employ optimal feedback controllers, which are often modeled by linear quadratic regulators, including the cases for analyzing human postural control (Kuo 1995). Optimization analysis would often result in gains of feedback

controllers located at the critical edge of stability (Milton et al. 2016), which could often lead to an emergence of power-law-like movement variability (Cabrera and Milton 2002).

A class of nonlinear feedback controllers with time-discontinuous, impulsive actions is an important alternative that can implement the minimum intervention principle for resolving the trade-off problem. An impulsive controller is indeed compatible with the minimum intervention principle, as it acts only during very brief periods of time. Moreover, because impulsive feedback actions are silent most of the time, no deviations from the motor goal are actively opposed, leading to the flexibility of the joint movements. The intermittent controller is a representative of such class of controllers. In recent years, a variety of different versions of the intermittent controllers have been proposed, mostly as computational models of balance control of an inverted pendulum and of postural control during human upright stance. The first version is detailed later in this chapter, which exploits the fact that the state point of the inverted pendulum transiently approaches the upright position along a stable manifold of an unstable saddle-type equilibrium of the off-system as defined above (Asai et al. 2009; Bottaro et al. 2008; Suzuki et al. 2012). The second version assumes anticipatory ballistic bias control (Loram et al. 2011), which has been mathematically modeled with a state predictor for compensating a feedback delay (Gawthrop et al. 2011). In this case, the anticipatory controller operates intermittently, where the intermittency ensures the computational time for the anticipation (Loram et al. 2012). The third version considers open-loop periods (off-periods) representing a sensory dead zone (Eurich and Milton 1996; Insperger and Milton 2014), in which a feedback control during the closed-loop periods (on-periods) with appropriate feedback gains is responsible for stabilizing the pendulum. The fourth version is similar to the third one and has been referred to as the “act-and-wait control,” by which a delay-induced unstable system can be stabilized by an appropriate placement of finite number of poles, if the off-period is larger than the delay time (Insperger and Stepan 2010). The

fifth version may be termed as the “noise-induced stabilization” with a state-dependent multiplicative motor noise (Cabrera and Milton 2002), which arises when the delay-affected system is tuned at, or near, the edge of stability and a critical control parameter is stochastically forced back and forth across the stability boundary.

A Single Inverted Pendulum as a Model of Upright Posture

In this sequel, the intermittent feedback control strategy is described in detail. To this end, we first establish a model of the standing human body simply using an equation of motion of a single inverted pendulum as follows.

$$I\ddot{\theta}(t) = mgh\theta(t) + T(t), \quad (1)$$

where I represents the moment of inertia of the human body around the ankle, θ the tilt angle, g the gravity acceleration, m the body mass, h the distance from the ankle joint to the center of mass of the body, T the total ankle torque, and $mgh\theta$ the linearized gravitational toppling torque for small θ during quiet stance. For the body parameter values, see Asai et al. 2009. For small values of θ and $\dot{\theta}$, it is quite natural, in terms of Taylor expansion of a general torque as a function of θ and $\dot{\theta}$, to consider a model of the ankle joint torque T at time t as follows.

$$T(t) = -K\theta(t) - B\dot{\theta}(t) + T_{\text{act}}(t) + T_{\text{noise}}(t), \quad (2)$$

where the first two terms on the right-hand side represent passive feedback torques generated by the intrinsic mechanical impedance of the ankle joint (K and B are the passive stiffness and viscosity, respectively) with no time delay. The third term T_{act} represents the active neural feedback torque determined by the central nervous system as a function of delay-affected tilt angle $\theta_{\Delta} \equiv \theta(t - \Delta)$ and angular velocity $\omega_{\Delta} \equiv \dot{\theta}(t - \Delta)$ with Δ being the feedback delay time due to the neural signal transmission. The last term T_{noise} is an endogenous, i.e., internal disturbance that is modeled here as a white

Gaussian noise with its standard deviation σ . The state space representation of Eq. 1 is as follows.

$$\frac{d}{dt} \begin{pmatrix} \theta \\ \omega \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ \frac{mgh-K}{I} & -\frac{B}{I} \end{pmatrix} \begin{pmatrix} \theta \\ \omega \end{pmatrix} + \frac{1}{I} \begin{pmatrix} 0 \\ T_{\text{act}} \end{pmatrix} + \frac{1}{I} \begin{pmatrix} 0 \\ T_{\text{noise}} \end{pmatrix} \quad (3)$$

where $\omega \equiv \dot{\theta}$, or formally

$$\frac{dx}{dt} = Ax + u(x_{\Delta}) + d \quad (4)$$

where $x = (\theta, \omega)^T$ and $x_{\Delta} = (\theta_{\Delta}, \omega_{\Delta})^T$. The terms Ax , u , and d define the vector field of the non-actively actuated mechanical system, the active feedback control vector, and the disturbance vector, respectively.

Dynamics of a Non-Actively Controlled Inverted Pendulum

According to the experimental evaluations of the passive ankle viscoelasticity (Casadio et al. 2005; Loram and Lakie 2002), we set as $K = 0.8 \text{ mgh}$ Nm/rad and $B = 4.0 \text{ Nms/rad}$ for passive stiffness and viscosity in Eqs. (2) and (3). Thus, $mgh-K > 0$ and the upright state $x = (0, 0)^T$ is an unstable equilibrium of saddle type (*the saddle point*), with

stable and unstable manifolds when no active control is provided, i.e., $u = 0$ (Asai et al. 2009).

Figure 3 shows the hyperbolic vector field around the saddle point, accompanied with the stable manifold W^s and the unstable manifold W^u . For the body parameter values used here, the stable and unstable manifolds of $dx/dt = Ax$ on the θ - ω plane are given, respectively, by the straight lines passing through the origin.

$$\omega = \lambda^- \theta \sim -1.434\theta \quad (5)$$

and

$$\omega = \lambda^+ \theta \sim 1.367\theta \quad (6)$$

where

$$\lambda^{\pm} = \frac{1}{2} \times \left(-B/I \pm \sqrt{(B/I)^2 + 4(mgh-K)/I} \right), \quad (7)$$

which are the eigenvalues of the system matrix A . Any state point exactly on the stable manifold approaches the saddle point, which takes infinite time, because the vector field becomes null as the

Intermittent Control Strategy for Stabilizing Human Quiet Stance, A Model of the,

Fig. 3 Hyperbolic vector field and sample trajectories of the single inverted pendulum model with no active feedback controllers. The origin is the upright equilibrium of saddle type (*the saddle point*), accompanied with stable manifold W^s and unstable manifold W^u

state point is close to the saddle point. Similarly, any state point near the stable manifold also approaches the saddle point transiently, which would provide convergent dynamics of the intermittent control model as described below. The state point approaching the saddle point, however, moves eventually away from the saddle point along the unstable manifold W^u .

Continuous and Intermittent Feedback Control Models

The traditional impedance control and the intermittent control strategies employ the same conventional proportional (P) and derivative (D) feedback controller (PD controller), but in a strongly different manner. The impedance control model uses the PD feedback control in a conventional manner, i.e., time-continuously, referred to here as the continuous controller. It generates the active feedback torque in Eqs. (2) and (3), denoted by $T_{\text{act}}^{\text{cont}}$ (Maurer and Peterka 2005). In this way, the continuous controller is defined as

$$T_{\text{act}}^{\text{cont}}(t) = -P\theta_{\Delta} - D\omega_{\Delta} \quad (8)$$

where P and D are the P and D gains, respectively.

On the other hand, in the intermittent control model, the PD feedback controller is switched on and off intermittently, depending on the delayed state of the pendulum x_{Δ} (Asai et al. 2009). The corresponding active feedback torque in Eqs. (2) and (3) is denoted by $T_{\text{act}}^{\text{int}}$ as defined later. For both cases, the feedback delay time is set as $\Delta = 0.2$ s according to the experimental evaluation by Peterka (2002).

The Continuous Feedback Control Model and Delay-Induced Instability

As in Eqs. (1), (2), and (8), the equation of motion for the inverted pendulum with the continuous delay feedback controller is rewritten here as

$$I\ddot{\theta}(t) = (mgh - K)\theta(t) - B\dot{\theta}(t) - P\theta(t - \Delta) - D\dot{\theta}(t - \Delta). \quad (9)$$

Taking Laplace transform of both sides with the zero initial condition, we have

$$Is^2\Theta(s) = (mgh - K)\Theta(s) - Bs\Theta(s) - P\Theta(s)\exp(-\Delta s) - Ds\Theta(s)\exp(-\Delta s), \quad (10)$$

where s is the Laplace variable and $\Theta(s) \equiv \mathcal{L}[\theta(t)]$, which yields the following characteristic equation:

$$s^2 + bs - k + ds\exp(-\Delta s) + p\exp(-\Delta s) = 0 \quad (11)$$

where $b = B/I > 0$, $k = (mgh - K)/I > 0$ when K is smaller than the load stiffness mgh , $d = D/I > 0$, and $p = P/I > 0$. This is a transcendental equation that has an infinite number of solutions and difficult to solve analytically. However, we can analyze p and d values, for a given delay Δ , at the critical edge of stability, where the real part of the characteristic roots $s = \sigma + j\omega$ is zero, i.e., $\text{Re}[s] = \sigma = 0$. At such instability points, $s = j\omega$, if ω is non-zero. By substituting this into Eq. (11), we have

$$p \cos(\omega\Delta) + d\omega \sin(\omega\Delta) - \omega^2 - k = 0 \quad (12)$$

$$b\omega - p \sin(\omega\Delta) + d\omega \cos(\omega\Delta) = 0 \quad (13)$$

Those equations can be solved for unknowns p and d , which are parameterized by ω , for finding critical feedback gains as follows.

$$\begin{pmatrix} p(\omega) \\ d(\omega) \end{pmatrix} = \begin{pmatrix} (\omega^2 + k) \cos(\omega\Delta) + b\omega \sin(\omega\Delta) \\ (\omega^2 + k) \frac{\sin(\omega\Delta)}{\omega} - b \cos(\omega\Delta) \end{pmatrix} \quad (14)$$

Note that, for $\omega = 0$ at the instability point, the characteristic equation becomes

$$-k + p = 0 \quad (15)$$

meaning that $p = k$ is the stability boundary. Depicting a curve on p - d plane, or indeed P - D plane for varied values of ω , together with $P = mgh/K$ (or $p = k$), we have a stability region of the continuous control model on P - D plane as shown in Fig. 4.

Intermittent Control Strategy for Stabilizing Human Quiet Stance, A Model of the, Fig. 4 Stability region (the gray region) of the continuous PD feedback control model with time delay ($\Delta = 0.2$ s). The open square represents a typical PD gain for the continuous PD feedback controller (the impedance control model). The open diamond is a typical PD gain used for the on-system of the intermittent control model, which is outside of the stability region of the continuous PD feedback control model

Typical gain values that have been estimated by previous studies and also used in this chapter are $P = 471$ Nm/rad, corresponding to 0.8 mgh, and $D = 275$ Nms/rad (Maurer and Peterka 2005). This parameter point $(P, D) = (471, 275)$ is located almost in the middle of a narrow stability

region in the P - D parameter plane. The upright posture $x = 0$ is asymptotically stable of focus type for those values. Maurer and Peterka reported that human postural sway data were best fitted by those values with a given colored torque noise of very large intensity (Maurer and Peterka 2005).

Figure 5a shows dynamics of the continuous control model with two different noise intensities ($\sigma = 0.2$ Nm for small noise case and $\sigma = 2.0$ Nm for large noise case). For the small noise case, the sway amplitude is very small, because the upright posture is rigidly stabilized by the continuous PD controller with the large gains at $(P, D) = (0.8$ mgh, 275). In this case, the tilt angle $\theta(t)$ of the model shows a white-noise-like variation. The sway amplitude becomes large as comparable as human postural sway for the large noise case. However, also in this case, the sway pattern shows a white-noise-like jitter. Indeed, PSDs at the low-frequency regime are almost flat, and the powers decrease steeply for the high-frequency regime, as shown in the bottom panels of Fig. 5.

The Intermittent Feedback Control Model

The intermittent feedback controller is defined as follows.

$$T_{\text{act}}^{\text{int}}(t) = \begin{cases} -P\theta_{\Delta} - D\omega_{\Delta}, & \text{if } (\theta_{\Delta}, \omega_{\Delta})^T \in S_{\text{on}}, \\ 0, & \text{otherwise if } (\theta_{\Delta}, \omega_{\Delta})^T \in S_{\text{off}}, \end{cases} \quad (16)$$

where S_{on} and S_{off} define the regions in the θ - ω plane, by which the state-dependent activation and inactivation of the active torque are determined. See Fig. 5b bottom right, in which S_{off} is represented by gray regions and S_{on} by white regions. The parameters P and D are, respectively, the P and D gains of the PD feedback controller when it is activated. The PD feedback controller is activated when the delayed state of the pendulum $x_{\Delta} = (\theta_{\Delta}, \omega_{\Delta})^T$ is located in S_{on} , while it is inactivated when x_{Δ} is in S_{off} . In (Asai et al. 2009), S_{on} and S_{off} are separated by the boundaries defined by $\theta_{\Delta} = 0$, $\dot{\theta}_{\Delta} = a\theta_{\Delta}$ and $\theta_{\Delta}^2 + \dot{\theta}_{\Delta}^2 = r^2$. The parameter r is fixed at 0.004 here, which determines the circular sensory dead zone around

the upright position. The parameter a determines the slope of the on-off boundary line $\dot{\theta}_{\Delta} = a\theta_{\Delta}$ ($a = -0.4$ in Fig. 5b). The parameters P and D of the PD controller, when the PD controller is activated, are set as $P = 147$ Nm/rad corresponding to 0.25 mgh and $D = 10$ Nms/rad in Fig. 5b. Note that the parameter set $(P, D) = (0.25$ mgh, 10) is outside of the stability region of the continuous control model, as indicated by the diamond-shaped symbol in Fig. 4. That is, if the intermittent controller were activated persistently regardless of the location of the state point, the upright equilibrium would be unstable of focus type, due to the delay-induced instability. Note also that these values are much smaller than P - D gains used for

(a) $P = 0.8mgh$, $D = 275$, $\sigma = 0.2$ and 2.0 (b) $P = 0.25mgh$, $D = 10$, $\sigma = 0.2$ 

Intermittent Control Strategy for Stabilizing Human Quiet Stance, A Model of the, Fig. 5 Typical sway dynamics with noise for (a) the traditional continuous control model and (b) the intermittent control model. In each of (a) and (b), top trace: a sample path of the tilt angle

θ for 60 s. Bottom left: power spectral density (PSD), which was estimated by ensemble average of five PSDs. Bottom right: phase portrait. (a) Noise intensities: $\sigma = 0.2$ Nm (black curves) and $\sigma = 2$ Nm (gray curves). (b) Noise intensity: $\sigma = 0.2$ Nm

the impedance controller, which provides a basis of flexibility of the ankle joint by means of the small joint impedance even when the active feedback control is switched on. Despite the fact that upright equilibrium is also unstable of saddle type when the intermittent controller is persistently switched off, it is remarkable that a switching between the activation and the inactivation of the PD feedback controller can establish a bounded stability of the inverted pendulum (Asai et al. 2009).

Figure 5b shows a typical steady-state dynamics of the intermittent control model with small noise ($\sigma = 0.2$ Nm). In contrast to the impedance control model, the sway pattern contains slow oscillatory component with an amplitude as large as human sway even with the small noise. The phase portrait of the model illustrates features of the intermittent control model, in which the state point x in the off-region S_{off} moves slowly along the stable manifold, approaching the saddle point transiently, followed then by the slow fall away from the saddle point along the unstable manifold until the state point goes out the off-region S_{off} . When the PD controller is activated in S_{on} , the delay-induced unstable oscillatory dynamics moves the state point closer to the stable manifold in the off-region, at which the PD controller is

switched off (see Fig. 5b bottom right). Since this scenario works for both right and left halves of the phase plane, the noisy dynamics exhibit transitions between left and right planes, in addition to the on-off transitions, generating a butterfly-shaped trajectory. The PSD for this fluctuation shows the power-law-like behavior at the low-frequency regime (Fig. 5b bottom right), where the regression line, representing the scaling exponent β , is close to $3/2$ as in human postural sway.

Flexibility Versus Rigidity

By comparing Fig. 2 with Fig. 5, the following similarities are evident: similarity between Fig. 2a for a healthy young adult and Fig. 5b for the intermittent control model and similarity between Fig. 2b for a Parkinson's patient and Fig. 5a for the continuous control model. Those similarities suggest that the upright stance of healthy young adults is stabilized flexibly by the intermittent controller, whereas that of a population of patients with Parkinson's disease is stabilized rigidly by the continuous controller. This might be a natural consequence of the selection of strategy for stabilizing the upright stance based on the minimum intervention principle with the trade-off problem regarding the minimization of the deviation from the upright posture and the minimization of the

energetic cost (Michimoto et al. 2016). However, it should be noted that multiple strategies could be adopted by different experimental subjects for a single goal of motor task, probably depending on the criteria used for adapting given tasks and environment (Zenzeri et al. 2014).

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms

J. Leo van Hemmen

Physik Department and Bernstein Center for Computational Neuroscience–Munich, Technical University of Munich, Garching bei München, Germany

Synonyms

[Internally coupled ears](#); [Pressure-difference receiver](#); [Pressure-gradient receiver](#)

Though the notions of pressure-gradient receiver and pressure-difference receiver have been used widely (van Hemmen et al. 2016, Sect. 2), they are not really synonymous with the “internally coupled ears” or for short ICE that we analyze here because, in contrast to ICE, both are ill-defined or even wrong. The pressure difference between the two eardrums never gives rise to a gradient since, for the terrestrial vertebrates under consideration, the interaural distance L is of the order of cm. A gradient means taking a derivative and, hence, a limit $L \rightarrow 0$ whereas in reality L is fixed and bound to remain finite >0 . Even though L is of the order of a few, usually <2 , cm and hence $\ll \lambda$, with λ as a wavelength relevant to sound localization, a finite L is essential to giving a finite time delay for all nonzero directions. The time delay between left and right eardrums is a cue, though not the only one, to azimuthal sound localization. Furthermore, pressure differences do not single out internally coupled ears since *all* vertebrates, including mammals with independent ears, use pressure differences between the two tympana to azimuthally localize a sound source. Since both terms are either wrong or do not cover the reality they are supposed to describe, it was decided during the international conference *Internally Coupled Ears* at the TUM Institute for Advanced Study, Garching bei München, Germany, June 18–20, 2014, to adopt the new name “Internally Coupled Ears.” For details, see the special issue of *Biological Cybernetics* 110/5–6 (2016) devoted to ICE; in particular, the Editorial (van Hemmen et al. 2016).

Definition

ICE stands for internally coupled ears. Frogs, lizards, crocodilians, and birds, more than half of the land-living vertebrates, possess ICE, where an air-filled internal cavity couples the two eardrums. Though many insects are also equipped with ICE, we will focus here on terrestrial vertebrates. When sound excites the two eardrums, the motion of each of them will induce a pressure wave in the internal or interaural cavity, which then propagates to the other eardrum, and modifies the

response to the incoming sound arriving there. The coupling between the two eardrums is reciprocal and changes the interaural (ITD and ILD) into *internal* time and level difference (iTD and iLD). An animal only perceives the latter. Its neuronal system uses both iTD and iLD for azimuthal sound localization. Hence the effect of ICE is twofold, on both iTD and iLD, and is often profound.

Detailed Description

Before embarking on the underlying mathematical description of ICE, we will review what is currently known about where internally coupled ears have come from through evolution, how widely they are distributed in nature, and what the internal coupling looks like for different groups.

ICE: Phylogeny and Appearance

As Fig. 1 shows, tympana appeared both rather early in evolution, independently in different groups, and the great majority of land-living vertebrates have internally coupled ears. Only mammals, snakes, Sphenodontidae (*Tuataras*), and the Testudines (reptiles commonly known as turtles, tortoises, and terrapins) have independent ears. Living mostly in water with a sound speed of more than four times that in air, they use the otoliths of the vestibular system as inertial masses to localize a sound source, as do fish (Teleosts) (Zeddies et al. 2011). Snakes are equipped with a unique auditory system (Friedel et al. 2008; Young 2003), which makes them feel happy in soil such as sand, with density a 1000 times bigger than that of air, and does not need Eustachian tubes to equilibrate inside and outside pressure. Mammals do need to equilibrate, but their Eustachian tubes are so thin and long that an effective coupling between left and right tympanic cavity does not exist – except for a few exceptions (Mason 2016) of mammals that live underground and by their very existence “prove” the rule.

Azimuthal sound localization is realized neuronally on the basis of what the animal actually hears. In animals with ICE, this is not the

interaural time and level (i.e., intensity) difference, ITD and ILD, generated between the two eardrums by external sound as stimulus, but the *internal* time and level difference, iTD and iLD, which are a consequence of the superpositions of external stimulus p_{ext} at the tympana and the internal, or interaural, cavity pressure p on the inside of the two eardrums that are coupled by the very same p .

Figure 1 already suggests a certain diversity in the geometry of the interaural cavity as present in different orders and this is confirmed by Fig. 2. Since the mere geometry of the cavity determines the resulting iTD and iLD that the animal perceives as superposition of the outside stimulus and the internal pressure at its tympana, we need to focus on the nature of the connective geometry, the essential part of ICE.

Figure 2a shows what the interaural canal looks like in frogs such as the American bullfrog *Rana catesbeiana* or the common frog *Rana temporaria* (Linnaeus, 1758). The pharynx is connected to both the lungs and to the middle ear or tympanic cavities through permanently open, but relatively narrow, Eustachian tubes. Only when croaking do frogs open their mouth and expand their pharynx. When localizing sounds, frogs have their mouth closed and pharynx constricted; their eardrums and middle-ear/tympanic cavities are coupled through their pharynx and Eustachian tubes.

Most frogs are amphibious and exhibit the above setup, but the South-African clawed frog *Xenopus laevis* is fully aquatic, except during rare overland migrations between ponds. We will see later on how the ICE system of *Xenopus* has adapted to this aquatic existence, where the speed of sound is 4.2 times bigger than in air so that iTDs for an interaural distance $L = 2$ cm are reduced to values so small that even ICE cannot make them neuronally manageable; see subsection “[Underwater Hearing and Sound Localization: The Case of *Xenopus*.](#)”

Figure 2b exhibits the pharyngeal cavity, the back part of the lizard’s mouth, which provides ample air, and space, to connect the two eardrums. Lizards are typical representatives of ICE and they have been studied extensively, first experimentally

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 1 Evolutionary origin of audition, with the vertical axis denoting time – top is modern times – and the horizontal direction for indicating natural diversity. Teleosts are fish, Dipnoi are lungfish, and the Anura stand for frogs. Snakes belong to the squamates but have independent ears so that the squamates need to be restricted to the lizards, a gigantic family. The Crocodylia have two, or more, interaural canals connecting the left and right tympanic cavities directly behind the eardrums. Many

birds show a rather intricately shaped interaural cavity with weird looking, supporting, “stalactites” so as to minimize turbulence and give the cavity more stability. Just take it as one canal. Entering the Tertiary the dinosaurs, to the left of the birds (Aves, together with the Crocodylia their relatives, so to say), stopped existing. Tympana appeared in the Triassic and so did ICE. (Figure taken from and modified after van Hemmen et al. (2016))

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 2

Schematic of internally coupled ears (ICE) in terrestrial vertebrates: (a) frogs, (b) lizards, (c) birds, (d) Crocodilians. The realizations are quite different. Frog and lizard are illustrated with coronal slices, as are crocodilians; the bird is shown in a transverse slice as a dorsal view from above. The (colored) tympana are surfaces bounding the air-filled interaural cavity, which physically couples the left and right eardrums. As shown explicitly in

(b), the extracolumella embedded into the eardrum transfers tympanic vibrations through the columella into the cochlea, which is connected to the auditory system, where sound localization is realized neurally. (d) Crocodilians have more than one canal (here one dorsal and two ventral canals, all labeled by 2) connecting the two ear drums, which are flanked by tympanic cavities (1). (Figures (a–c) have been taken from Christensen-Dalsgaard (2005), in a slightly different version due to van Hemmen et al. (2016))

(Christensen-Dalsgaard and Manley 2005, 2008) and then theoretically in terms of mathematical models first for lizards (Vossen et al. 2010), then in far more detail both for lizards (Vedurmudi et al. 2016a) and for nearly all “icy” animals (Vedurmudi et al. 2016b, 2018). The extracolumella is embedded in the eardrum. The columella, which is directly connected to the former and makes a 90° angle with both, then transfers the tympanic motion to the cochlea.

Finally, Fig. 2c, d show the situation in extant archosaurs, viz., birds and crocodilians, the only known survivors of a larger group to which the dinosaurs also belonged. Whereas frogs and lizards exploit a single interaural cavity or canal to connect the left and right eardrums, crocodilians possess two or more canals; generically, a rather robust dorsal one and one or two ventral ones. The latter are connected to the pharyngeal cavity through the median pharyngeal valve and in this way also function as Eustachian tubes that equilibrate interaural and outside pressure, the valve only opening during a short period of time, say, 0.3 s, approximately every 120 s (Young and Bierman 2019). So its opening is sparingly dosed.

Performance of Internally Coupled Ears (ICE)

Why did nature equip more than half of the terrestrial vertebrates with ICE? Let us analyze the performance of ICE as shown by lizards, a generic case. Sound localization is due to a *neuronal*

evaluation of sound stimuli that arrive at left and right eardrums. As we have seen, the animal does not perceive the interaural but the internal time and level differences, iTD and iLD. Here we focus on azimuthal sound localization, in a horizontal plane at the center of which we imagine the animal. For what follows, a clear definition of both iTD and iLD is crucial. For the iTD things seem, and are, clear. There is, however, an important derived quantity, the *time dilation factor* or for short $TDF = iTD/ITD$. For lizards the TDF is typically of the order of 3 so that their *effective* interaural distance is not L but $3L$.

The outside stimuli arrive at an angle θ with respect to the rostral-caudal axis through the animal so that $\theta = 0$ is straight in front. Once the source is far enough away, the time difference between left and right eardrums is to good approximation $\Delta = (L \sin \theta)/c$ where c is the speed of sound in air. For generic lizards, $L \simeq 1 - 2$ cm. They therefore face a problem: For their neuronal hardware Δ is too small, even for $\theta = 90^\circ$, to get a decent accuracy; say, $10-20^\circ$. It is here that ICE come(s) in to help.

Let us turn to Fig. 3, showing the generic ICE performance. The left vertical axis is for the dimensionless fraction $iTD/ITD = TDF$, the time dilation factor, while the right vertical axis is for the iLD, dimensionless too. Both are shown as a function of the frequency of a pure-tone stimulus, indicated by the horizontal axis. The cochlea

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 3 Performance of ICE, schematic. The time dilation factor $TDF = iTD/ITD$ (left vertical axis, blue) and the internal level difference iLD (right vertical axis, red) are shown as a function of frequency f , plotted along the horizontal axis. Both are shown for stimulus directions $\theta = \pm 90^\circ$. The fundamental frequency f_0 of the eardrum is indicated on the horizontal axis, here slightly beyond 1.0 kHz, and corresponds to that of the Tokay gecko, the second-largest gecko. On the other hand, in the house gecko (*Hemidactylus*) $f_0 \approx 2.8$ kHz. Typically, the TDF exhibits a plateau up to about 3 for $0 \leq f \leq 2f_0/3$, and then drops to 0. TDF values of 4 and more (e.g., for *Crocodylia*) are also known. The frequency interval $[0, 2f_0/3]$ is well within the range of hair-cell phase locking (up to 1.5 kHz) that is needed for neuronally evaluating the iTD obtained from the cochlea. On the other hand, slightly beyond f_0 , say at $1.1 f_0$, the iLD shows a maximum, which may be of the order of 10–20 dB, even though the iLD vanishes. (Figure taken from Vedurmudi et al. (2016a))

makes a frequency decomposition (of a kind we need not discuss here) and tympanic amplitudes are extremely small (in the range of nm; Nature is not a disco) while the velocities are of the order of μ m/s. Linear acoustic theory is therefore applicable (see below) and we can treat the general sound stimulus as a linear superposition of pure tones.

The tympanum is the gate between the outside auditory world and the internal pressure coupling the two eardrums through the interaural cavity. Its fundamental frequency will be called f_0 . To the left of $2f_0/3$ we see in Fig. 3 that the fraction $iTD/ITD \equiv TDF$ exhibits a plateau at a level appreciably bigger than 1. It is typically 3 for lizards but, for instance for *Crocodylia*, it may well assume a value between 4 and 5. Beyond $2f_0/3$, where the $2/3$ is also an estimate that is easy to remember, the TDF drops down to 0 and is worthless for azimuthal sound localization because the hair cells' phase locking is over beyond, typically, 1.5 kHz. The barn owl

(Konishi 1993; Köppl and Carr 2008; van Hemmen 2002) is one of the famous exceptions proving the rule as its phase-locking upper bound is about 9 kHz.

The plateau shown in Fig. 3 is only for the sound-source directions of $\pm 90^\circ$ but the plateau height assumes the same value for all directions (Vedurmudi et al. 2016b, 2018). Hence the neuronal processing ensuing from the cochlea can start, so to speak, with a frequency input that has constant TDF, which makes the ensuing auditory processing workable. For lizards, the plateau value of 3 agrees with experiment (Christensen-Dalsgaard and Manley 2008).

As Fig. 3 shows, when the TDF starts decreasing steeply (to values near 0), the iLD begins to increase and may well assume an appreciable maximum of 10–20 dB. It does so at a frequency slightly beyond f_0 say, at $1.1 f_0$. Most “icy” animals, certainly nearly all lizards, experience a practically vanishing $iLD \approx 0$ because the head does not screen for the wavelengths at stake, with $L \ll \lambda$. Nevertheless, despite a negligibly small external iLD , the accompanying iLD may well become quite large for larger angles, as shown in Fig. 3 for adult animals with sound-source direction of $\pm 90^\circ$ or, equivalently, $\pm \pi/2$.

In summary, through ICE the animal's auditory system obtains two clearly disjoint frequency regimes. First, a low-frequency one, with $0 \leq f \leq 2f_0/3$ where the fraction $TDF = iTD/ITD$ shows a plateau. As noted, here the TDF obtains – for adult lizards – typical values of 3 (but may well become 4–5 in other reptiles). This solves the small-animal problem (Christensen-Dalsgaard and Manley 2014, p. 183) in which the head and, more importantly, the interaural distance L or with θ as direction the $ITD = L \sin \theta$ of most “icy” animals are too small to come up with what one may call a decent value. It can be shown (Vossen 2010, Fig. 3.4) that a TDF of about 3 may give rise to a precision of 10–20°. The argument, however, provides an existence proof but not more than that, because the underlying neuroanatomy is not yet known. Jeffress (Konishi 1993; van Hemmen 2002; Köppl and Carr 2008) sounds plausible but it may be different.

Second, at higher frequencies ICE equips the auditory system with an iLD maximum at about $1.1 f_0$ and, despite $ILD \approx 0$, with iLD values that may well be between 10 and 20 dB; cf. Fig. 3. Turning the head so as to seek the direction of a sound source is quite often observed in animals with ICE, among others in birds. That is, the iLD allows for sound-source detection, though not a fast one.

Finally, and as anatomical confirmation of our discerning iTDs and iLDs, lizards possess a neat split-up of their hair cells (Manley 2000) into low- and high-frequency ones. The former are specialized in timing, the latter in amplitude cues. Following their respective axons, one sees (Szpir et al. 1990; Willis et al. 2014) a bifurcation into disjoint parts of the auditory system, which are functionally consistent with this split-up.

Mathematical Analysis and Explanation

It is now more than timely to show what principles underlie the mathematical analysis of ICE. As a mathematical abstraction we replace the internal cavities of Fig. 3 by cylinders, such as the one in Fig. 4a.

Tympanic membrane Let p be the pressure of the interaural or internal cavity Ω_i , which connects

the two eardrums and, hence, is a three-dimensional bounded domain in $\mathbb{R}^3$, with smooth boundary $\partial\Omega_t$, both Ω_t and its border $\partial\Omega_t$ depending on time t once a stimulus sounds loudly enough to set the eardrum into motion. The tympanic membrane's dynamics is given by a two-dimensional damped wave equation,

$$-\frac{\partial^2 u}{\partial t^2} - 2\alpha \frac{\partial u}{\partial t} + c_M^2 \Delta_{(2)} u = \frac{1}{\rho_m d} [p(x, r, \varphi; t) - p_{\text{ext}}(x, r, \varphi; t)]|_{x=0,L} \quad (1)$$

where $\Delta_{(2)}$ is the two-dimensional Laplacian, u is the membrane's deviation from the equilibrium $u \equiv 0$, measured along the x -axis, α is the damping coefficient, c_M is the membrane's transverse-wave propagation velocity and $[p(x, r, \varphi; t) - p_{\text{ext}}(x, r, \varphi; t)]$ is the total pressure on the eardrum surface driving the membrane at either end $x = 0, L$. Here p_{ext} is the external pressure due to a sound stimulus while p is the internal pressure coupling the tympana. The prefactor $1/\rho_m d$ with ρ_m as the membrane's density and d as its thickness is in fact a dimensional one.

In passing we note that, without external input, that is, with $p_{\text{ext}} = 0$, but with $\alpha > 0$, as in realistic eardrums with damping, the coupled eardrum-air system relaxes to the equilibrium state $u \equiv 0$ &

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 4

(a) Because of the coupling of the eardrums through the internal cavity, an animal equipped with ICE perceives internal rather than interaural time and level differences. The interaural cavity IAC is modeled mathematically as a cylinder of volume V_{cav} and of length L with radius $a_{\text{cav}} \equiv \sqrt{V_{\text{cav}}/\pi L}$; L is also the interaural distance. Cylindrical coordinates are used, with x -axis as cylinder axis parallel to the arrow $(0, L)$ and the polar coordinates $\{r, \varphi\}$ in a plane

orthogonal to it. The smaller (red) circles at either end indicate the eardrums with radius $a_{\text{tymp}} \leq a_{\text{cav}}$. The dark-gray wedge between $\varphi = \pm\beta$ stands for the extracolumella (Vedurmudi et al. 2016b, Fig. 1), which is embedded in the eardrum and is connected with the cochlea through the columella. As indicated in (b), it is practically orthogonal to the extracolumella. (Figures modified after Vedurmudi et al. (2016a) and Christensen-Dalsgaard and Manley (2019), respectively)

$p \equiv 0$. For p there is a three-dimensional wave equation to which we will turn in a minute. Its boundary conditions are governed by Eq. (1) where p appears as source term, a feedback coupling.

Damping as described by Eq. (1) has never been derived as such but is standard and known to be realistic. It leads to an exponential decrease of u as $\exp(-\alpha t)$ where $1/\alpha$ is of the order of one millisecond (ms) so that eardrums are fairly heavily damped, far more heavily than one naively imagines. Since the amplitudes induced by natural sound are in the nm range, with nearly always a maximum of 100 nm, and the eardrum radius a_{tymp} – see Fig. 4a – is in the cm range, tympanic motion can be taken to be purely normal so that only a single degree of freedom remains, viz., u .

In lizards – see for instance Fig. 4 and Vedurmudi et al. (2016b, Fig. 6) – an eardrum can be modeled to fair precision as a circular disk (Manley 1972; Vedurmudi et al. 2016b) with radius a and Dirichlet boundary conditions $u(a_{\text{tymp}}, \varphi) = 0$ at the edge $\{r = a_{\text{tymp}}\}$, including an effectively very heavy cartilaginous sector with boundaries $\varphi = \pm\beta$, which is called extracolumella. The composite system of extracolumella and columella is shown schematically in Fig. 4b. It transports membrane vibrations, which are virtually perpendicular to the eardrum, to the cochlea through the columella, which is practically orthogonal to the extracolumella embedded in the membrane and picking up its vibrations.

Internal cavity The internal pressure p in the cavity Ω describes the dynamics of air. Under normal circumstances the corresponding wave equation for sound has been derived through linear perturbation theory on the basis of the Euler equation (Acheson 1990; Rienstra and Hirschberg 2019; Temkin 1981) so that only the normal derivative $\partial_n p$ at the boundary $\partial\Omega_t$ needs to be specified. Amplitudes of natural sound are nearly always small, that is, in the nm range, while the membrane curvature remains small too, that is, of the order of $10^{-7}/10^{-3} = 10^{-4}$, which is an extremely conservative estimate. Accordingly, during the course of time any normal derivative $\partial p/\partial n$ simply equals $\partial p/\partial x$, and thus $\partial p/\partial n = \partial p/\partial x$ to high precision.

It is here that (linear) acoustics (Acheson 1990; Rienstra and Hirschberg 2019; Temkin 1981) comes in.

Since the boundary $\partial\Omega$ depends on the time t once sound sets the eardrums into motion, we need to say more and must specify boundary conditions for our partial differential equations (3) and (4) below. Now the no-slip boundary condition (Acheson 1990; Rienstra and Hirschberg 2019; Temkin 1981) comes into play in that at the boundary the macroscopic gas velocity and, hence, both normal and tangential components of the velocity vector $\mathbf{v}$ equal those of the (rigid) boundary itself. Experts might grumble that the corresponding wave Eq. (3) below is based on the three-dimensional Euler equation that only takes the normal derivative into account. True, but the no-slip boundary condition has been shown to be universally valid. That is, dropping second-order terms from the Euler equation near/at the boundary, we are left with

$$\frac{\partial p}{\partial x} = -\rho \frac{\partial v}{\partial t} \quad (2)$$

where ρ is the density of air and v is the normal velocity of the tympanic membrane the air sticks to according to the no-slip boundary condition (Acheson 1990), which has been confirmed experimentally since long. From Eq. (1) and its underlying physics we know that $v = \partial u/\partial t$ is the normal derivative to high precision (at least first order) so that the circle is closed.

On the other hand, p satisfies the three-dimensional wave equation

$$\Delta_t p = \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} \quad (3)$$

where c is the speed of sound in air and Δ_t is the three-dimensional Laplacian on Ω_t as the time dependence is in the domain Ω_t . We may rewrite (3) in cylindrical coordinates,

$$\begin{aligned} \frac{1}{c^2} \frac{\partial^2 p(x, r, \phi; t)}{\partial t^2} &= \Delta_{(2)} p(x, r, \phi; t) \\ &+ \frac{\partial^2 p(x, r, \phi; t)}{\partial x^2} \end{aligned} \quad (4)$$

with $\Delta_{(2)} = \partial^2/\partial r^2 + (1/r)\partial/\partial r + (1/r^2)\partial^2/\partial \phi^2$ as the two-dimensional Laplacian in polar coordinates $\{r, \phi\}$; cf. Fig. 4a. The boundary condition (2) of Δ_t lives on $\partial\Omega_t$ and hence depends on the time t , as does the cavity's shape $\partial\Omega_t$ through the fluctuations of the eardrums. As for the rest, “the rest is silence” because most of the boundary is thin skin covering bone, so that the *remaining* part of the boundary is taken to be fixed and we can use Neumann boundary conditions with vanishing normal derivative; viz., $\partial_n p = 0$; see also (2) with $v = 0$.

Systematic perturbation theory Since the amplitudes of eardrum fluctuations are so small (<100 nm $\ll L$), a systematic perturbation theory sounds (van Hemmen 2016), and is (Heider and van Hemmen 2020), reasonable. Here we only analyze its key ideas. We start with the equilibrium configuration Ω_o where $u \equiv 0$ and $p \equiv 0$. Since the eardrum dynamics is (heavily) damped there is no harm in assuming $\Omega_t \subset \Omega_{\max}$, the latter set being only slightly bigger than Ω_o . The mathematical scenery we will meet here can now be imagined to live in the fixed Hilbert space $L^2(\Omega_{\max})$. We therefore proceed without further ado, referring the mathematically interested reader to elsewhere (Heider and van Hemmen 2020).

We write the volume change as $\Omega_t = \Omega_o + \kappa\delta\Omega$ with the $+$ as a formal plus sign for sets, $\delta\Omega$ as the symmetric difference between Ω_t and Ω_o with indicator function $1_{\delta\Omega(t)}$, and κ originating from Ω_t and Ω_o as a clever $\pm$ that makes Ω_t out of Ω_o : If Ω_o is smaller, we add, and if Ω_o is bigger, we subtract; see below. The time-dependent Eq. (3) then reappears in the form

$$\begin{aligned}\partial_t^2 p &= \Delta_t p = [\Delta_o + \kappa(1_{\delta\Omega}\Delta 1_{\delta\Omega})]p \\ &\equiv [\Delta_o + V(t)]p\end{aligned}\quad (5)$$

where the perturbation $V(t)$ directly stems from the volume fluctuation, which induces addition or subtraction of a piece of the Laplacian to or from the “Laplacian cake” based on Ω_o . Moreover, the Δ sandwiched by the $1_{\delta\Omega}$'s in Eq. (5) is the Laplacian as a mere partial-differential operator in our big, fixed, Hilbert space $L^2(\Omega_{\max})$. In other words, in view of Eq. (5) we can also write formally (and a bit more suggestively)

$$\Delta_t = [\Delta_o + \kappa(1_{\delta\Omega}\Delta 1_{\delta\Omega})]. \quad (6)$$

By the way, the operator

$$(1_{\delta\Omega}\Delta 1_{\delta\Omega}) \equiv \Delta|_{\delta\Omega(t)} \quad (7)$$

is the Laplacian restricted to the fluctuating domain $\delta\Omega(t)$, an operator that – despite a slight misuse of language – effectively does what it formally looks like.

Duhamel principle Second derivatives such as $\partial_t^2 = \partial^2/\partial t^2$ in Eq. (5) are nearly always a nuisance but there is an old trick to get rid of them and reduce everything to a single differentiation with respect to time t . To this end we define the two-component vector $\mathbf{p} \equiv (p, \partial_t p)$ so that $\partial_t \mathbf{p} = (\partial_t p, \partial_t^2 p)$. For a two-vector $\mathbf{p}$ we get two equations instead of one and introducing matrix operators carrying a tilde we readily find

$$\partial_t^2 p = \Delta_t p \Rightarrow \partial_t \mathbf{p} = [\tilde{\Delta}_o + \tilde{V}(t)]\mathbf{p} \quad (8)$$

where $\tilde{\Delta}_o$ and $\tilde{V}$ are simple 2×2 matrices containing Δ_o and V in addition to 0 and 1 (zero and unit operators) as matrix elements. In a similar vein, Eq. (4) can be reduced to a first-order equation as well. In this way, we can take into account the physical variation of the cavity domain $\Omega(t)$ as a consequence of the eardrum or whatever membrane variations, which are always very small, and the right-hand side of Eq. (6) then directly leads to the Duhamel principle (Yosida 1980), whose key idea is worth considering.

If $\tilde{V} \equiv 0$, Eq. (8) is easy to solve by means of the semigroup $T_t^o = \exp(t\tilde{\Delta}_o)$ (Engel and Nagel 2006) so as to obtain $\mathbf{p}(t) = \exp(t\tilde{\Delta}_o)\mathbf{p}(t=0)$. Just differentiate. The initial condition $\mathbf{p}(t=0)$ is what we start with. Let us define $\mathbf{f}(t) = \tilde{V}(t)\mathbf{p}(t)$ and rewrite (8) in the form $(\partial_t - \tilde{\Delta}_o)\mathbf{p} = \mathbf{f}$. Once $\tilde{V} \neq 0$ we can still solve (8) formally through the Duhamel formula,

$$\begin{aligned}(\partial_t - \tilde{\Delta}_o)\mathbf{p} &= \mathbf{f} \Rightarrow \mathbf{p}(t) \\ &= T_t^o \mathbf{p}(0) + \int_0^t dt' T_{t-t'}^o \mathbf{f}(t')\end{aligned}\quad (9)$$

It is a straightforward exercise to verify that the expression on the right of Eq. (9) indeed solves the partial differential equation on the left. We simply note that t appears twice in the integral on the right and that the initial condition $\mathbf{p}(0)$ is satisfied by construction. Equation (9) embodies what is often called the Duhamel formula (Yosida 1980, §XIV.5). The semigroup T_t^0 is a continuous one (Engel and Nagel 2006) so that the integral in Eq. (9) is nothing esoteric but can be taken in the sense of Riemann.

One might complain that the solution we are looking for has been hidden in $\mathbf{f}$, which is correct. The idea of Dirac's perturbation theory (Dirac 1958, §§44–46) is to start with a zeroth-order solution we know for sure, for example, $\mathbf{p}(0)$, substitute that into the right-hand side of Eq. (9) so as to obtain $\mathbf{f}(t') = \tilde{V}(t')\mathbf{p}(0)$, and either happily stop or iterate. The “small stuff” is in $\tilde{V}(t)$. Whereas a plethora of books on quantum mechanics, including godfather Dirac's fascinating classic (Dirac 1958), write out everything componentwise in terms of eigenfunctions of $\tilde{\Delta}_0$ – the present author is not aware of any exception – the above representation (9) is far more efficient as it is neatly compact. For details we refer to elsewhere (Heider and van Hemmen 2020, §§2.2–2.4).

The above kind of perturbation theory is called *geometric* perturbation theory because it is based on the mere geometry of the cavity Ω_t as shown for instance in Figs. 2 and 4, and its boundary $\partial\Omega_t$ as it fluctuates during a sound stimulus. The eardrum fluctuations induce slight volume changes and these are taken into account through a series expansion based on Eq. (9). The mathematics as given by Eqs. (1), (2), and (3) then unfolds. It goes without saying that for sound in natural circumstances a single first-order term does the job to satisfying precision (Heider and van Hemmen 2020, §4).

Boundary conditions (2) Partial differential equations such as Eqs. (3) and (4) need side conditions, viz., initial and boundary conditions. When sound starts sounding at $t = 0$, $p(t) = 0$, and $u(t) = 0$ for $t \leq 0$ directly give us initial conditions at $t = 0$ for p and u and whatever (left) derivative.

What, then, are the boundary conditions of Eq. (2)? As background, Shearer and Levy (2015, §6.2.2) provide very useful information through their textbook treatment of an inhomogeneous time-dependent boundary-value problem, including convergence questions associated with the Gibbs phenomenon. This is the modern way where boundary conditions are treated as source terms. The interpretation is ours but the argument below is exactly what is happening there – and at many other places in modern PDE theory.

For whatever $\Omega(t)$, its boundary $\partial\Omega(t)$ is pretty smooth, up to the eardrum's border. The tympanic rim is fixed, hence gives rise to the Dirichlet boundary condition $u = 0$ at the rim, but biological physics dictates that there is no moment transfer either. In other words, the rim is fixed but the tympanum can rotate freely. Hence a discontinuity in the normal derivative may well occur but it does so on a set of (2-dim.) Lebesgue measure zero. So why bother? The two-dimensional manifold $\partial\Omega(t)$ is effectively smooth.

A systematic perturbation theory starts with a zeroth-order term, which is here $p^{(0)} \equiv 0$. To obtain the first, non-zero, contribution $p^{(1)} \equiv p$ we begin with a three-dimensional Laplacian Δ_t with Neumann boundary conditions ($\partial_n p = 0$) and with an extra source term ($\mathbb{F}$ below) that allows for both efficient bookkeeping of the time-dependent boundary conditions (2) and for using the Duhamel expression (9),

$$\frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} - \Delta_t p = \mathbb{F} \quad (10)$$

where $\mathbb{F}$ incorporates the time-dependent boundary conditions stemming from Eq. (2),

$$\mathbb{F} = \rho_0 c^2 [(\partial_t^2 u_0)\delta(\mathbf{x} \in u_0(t, \Gamma_0)) + (\partial_t^2 u_L)\delta(\mathbf{x} \in u_L(t, \Gamma_L))] \quad (11)$$

with Γ_0 and Γ_L denoting the left and right eardrums at $x = 0$ and $x = L$. Moreover, $\delta(\mathbf{x} \in \dots)$ is a Dirac-type delta measure located at the manifold $\Gamma_0 \subset \partial\Omega_0$ and $\Gamma_L \subset \partial\Omega_0$ while the prefactors $(\partial_t^2 u_0)$ and $(\partial_t^2 u_L)$ prescribe the value of p at the tympanic membrane in accordance with the

boundary condition (3). Here we stay in the context of first-order perturbation theory so that we end up with $\partial\Omega_0$. We note that the dynamics is now “stored” solely in the membrane displacements u_0 and u_L and no longer implicitly in the geometry.

Furthermore, in lowest nontrivial order of perturbation theory, with zeroth-order $p^{(0)} \equiv 0$, only the external pressure signal p_{ext} drives the membranes. The lowest-order contribution $u_{0/L}^{(0)}$ to the membrane equations consistent with the previously introduced perturbation theory is now given by (Heider and van Hemmen 2020)

$$\begin{aligned} \frac{\partial^2 u_{0/L}^{(0)}}{\partial t^2} + 2\alpha \frac{\partial u_{0/L}^{(0)}}{\partial t} - c_m^2 \Delta_2 u_{0/L}^{(0)} \\ = \frac{p_{\text{ext}}}{\rho_m d} \Big|_{x=0/L} \quad \text{on } \Gamma_{0/L} \subset \partial\Omega_0. \end{aligned} \quad (12)$$

Together with the wave Eq. (10) for the cavity pressure p , this has the effect of decoupling the ICE equations in lowest-order perturbation theory.

Extensions

We have seen in section “Performance of Internally Coupled Ears (ICE)” that ICE is quite a powerful mechanism in that, among others, it solves the small-animal problem at no cost of energy. It is now time to discuss a few extensions of the formalism that throw new light on the underlying biological physics of the eardrum through underwater hearing of *Xenopus* and on possibilities that have not been analyzed as such yet such as varying the fundamental frequency f_0 at will. As we have seen in Fig. 3, f_0 plays a key role.

Underwater Hearing and Sound Localization: The Case of *Xenopus*

As noted, tympana of animals with ICE function as gates between the outside auditory world and the internal pressure coupling the two eardrums through the interaural cavity. As Fig. 3 evidences, its fundamental frequency f_0 segregates the low-

frequency iTD plateau from the high-frequency iLD maximum (of course only for angles $\theta \neq 0$). We now focus on the African clawed frog *Xenopus laevis laevis*, which lives in Africa south of the Sahara. Except for rare overland migrations between ponds, the frog is fully aquatic. The speed of sound in water is, however, 1480 m/s (i.e., 4.3 times larger than in air) and *Xenopus*’s interaural distance $L \approx 20$ mm so that iTDs are too small to be determined neuronally. Nevertheless the frog uses its auditory system to localize its sexual partner underwater, that is, for mating. Mating is not a millisecond affair so that iLD determination by quietly rotating the head is possible. In other words, the frog can afford to azimuthally localize the source of a mating call.

There are two big differences between a generic ICE case such as a lizard one and *Xenopus* (Vedurmudi et al. 2018): (i) Instead of a flexible membrane, *Xenopus*’s eardrum is a stiff, cartilaginous, plate suspended in an elastic rim; (ii) the interaural cavity is a narrow Eustachian tube (with radius $a_{\text{ann}} = 0.4$ mm (Vedurmudi et al. 2018, Table I)), in the middle connected to the lungs, which function as a Helmholtz resonator with fundamental frequency of about 1.7 kHz. As underwater animal, *Xenopus* needs a separate, air-filled, interaural tube since under normal circumstances the pharyngeal cavity as part of the mouth is filled with water. The two shallow tympanic cavities have a distinct taper into the much narrower, shared, Eustachian tube. So to speak, *Xenopus* is the opposite of the lizard case depicted in Figs. 2b and 4a.

Lungs as Helmholtz resonator Given the above geometry, we now turn to its performance (Vedurmudi et al. 2018). Figure 5 evidences that inflated lungs that function as Helmholtz resonator (Rienstra and Hirschberg 2019) are essential in explaining the experimental data. The frog has a rich vocal repertoire (Müller and Scheer 1970; Tobias et al. 2011) with two peaks, one at about 1 kHz and another one at 1.7 kHz. Receptive females approach calling males (Picker 1983). Hence they do need sound localization. The peak at about 1 kHz calls the attention of receptive females but, as is evident from Fig. 5, a female cannot localize the calling male since the

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 5 Experimentally measured (filled triangles) and model vibration velocities (solid lines) of the clawed frog *Xenopus* (a) ipsilateral and (b) contralateral eardrum underwater. The eardrum vibration velocities have been measured (Christensen-Dalsgaard and Elepfandt 1995) by using laser vibrometry. The solid (red) line corresponds to inflated lungs with a total volume $V_H = 1.5$ cc and the

dashed (black) line corresponds to the case $V_H = 0$ cc, that is, absent or fully deflated lungs. The sound-source direction is $\theta = 90^\circ$. The contralateral amplitude is significantly lower than the ipsilateral amplitude. As both plots show, the experimental results can be explained only with inflated lungs, whose Helmholtz-resonator function has been analyzed by Vedurmudi et al. (2018) in great detail. (Figure courtesy of Vedurmudi et al. (2018))

difference between ipsi- and contralateral ear is none. At 1.7 kHz, however, there is an outspoken difference (about 15 dB) and it is due to the inflated lungs (Vedurmudi et al. 2018) that operate as a Helmholtz resonator with fundamental frequency of about 1.7 kHz, whose resonance is fairly sharply peaked. The female can, however, tune in to it by reducing its lung volume from, say, 2 to 1 cc (Vedurmudi et al. 2018, Fig. 10b).

Tympanum as disk instead of flexible drum: *Xenopus2* The 1 kHz regime being eminently important to arousing the female's attention, a natural question is whether and, if so, why a "normal" eardrum would not do the underwater job. To answer this question, a novel frog has been raised (Vedurmudi et al. 2018), *Xenopus2*. It is identical to the normal *Xenopus*, except for having a lizard-like, flexible, eardrum instead of a cartilaginous tympanic disk, as does traditional *Xenopus*. Figure 6 shows *Xenopus2*'s iLD localization performance.

Returning to Fig. 5 we now see that the tympanic disk gives rise to the 1 kHz peak arousing a female *Xenopus*'s attention in a frequency domain that is beyond that (<500 Hz) of ordinary predatory/prey detection but that by itself cannot discern left/right from straight ahead. On the other hand, *Xenopus2* is facing a nasty problem in that

underwater its attentive zone is around 200 Hz (Fig. 6a), which is exactly there where it should not be – except as predators' food. In air, which is what a lizard-like eardrum has been made for, the maximum is at about 350 Hz, but overland trips are only good for seldom, collective, moves from one pond to the next. In passing, *Xenopus*'s foraging time is mainly sunset or sunrise, while it is at the surface of the pond, hunting for insects that have dropped on the water surface and – in vain – struggle for life. In such a case, the frog's lateral-line system performs the prey detection.

Its lungs function as Helmholtz resonator with fundamental frequency of 1.7 kHz, and they equip the clawed frog with a clear difference of about 15 dB between left and right tympanum (for directions $\theta = \pm 90^\circ$) exactly near this 1.7 kHz. Though the frequency window is narrowly spaced, by reducing its lung volume a female *Xenopus* can easily perform a fine-tuning (Vedurmudi et al. 2018, Fig. 10b) so that an a priori perfect fit is not required. Once the access to the lungs is closed or once they have been emptied ($V_H = 0$), Fig. 5 shows that there is only a single maximum with no intensity difference between left and right eardrums. Hence the female *Xenopus* could hear but could not localize the "singing" male, too sad a story to be true.

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 6 Frequency dependence of the power absorption (dB re nW) by the ICE system of *Xenopus* (solid line) and *Xenopus2* (dashed line) for a lung volume $V_H = 1.5$ cc (a) underwater and (b) in air. The solid (blue) line corresponds to *Xenopus* as it exists in nature with rigid-plate eardrums, whereas the dashed (red) line corresponds to the computer-raised *Xenopus2* with thin, flexible, eardrums as

in lizards. Both have the same interaural cavity. Whereas *Xenopus* has a clear underwater maximum at 1 kHz, its companion *Xenopus2* has a peak at about 200 Hz, which is no good for survival since normal underwater predator/prey life happens in the low-frequency regime < 500 Hz. In all cases the sound-source direction is $\theta = \pm 90^\circ$. By varying its lung volume V_H , *Xenopus* can fine-tune the resonances of (a) and (b). (Figure courtesy of Vedurmudi et al. (2018))

Internally Coupled Ears (ICE): Biophysical Consequences and Underlying Mechanisms, Fig. 7 Variation of (a) time dilation factor ($TDF = iTD/ITD$) and (b) internal level difference (iLD) with the membrane frequency f_0 for an eardrum of the lizard *Varanus* with the damping fixed at $\alpha = 1.05$ (ms^{-1}) Hz. Increasing the fundamental frequency f_0 extends the TDF plateau but at the same time reduces its height. On the other hand, the

iLD peak height decreases only slightly with an increase in the fundamental frequency, whereas the location of the peak shifts linearly with f_0 . Both figures indicate the possibility of tuning the sensitivity to sound localization cues by changing the tension of the eardrum; for instance, by contraction of the tympanus muscle (Vedurmudi et al. 2020)

Tuning the Eardrum's Fundamental Frequency

We now return to “ordinary” animals with ICE such as lizards. Intuitively, the fundamental frequency f_0 of an eardrum increases as $\sqrt{T}$ with increasing

tension T of the tympanic membrane. In fact, one can show (Vedurmudi et al. 2020, Eqs. (3)–(5)),

$$f_0 = \frac{c_M \mu_{11}}{2\pi} = \frac{\mu_{11}}{2\pi} \sqrt{T/\rho_M d_M} \quad (13)$$

where c_M is the propagation speed of waves in the membrane, μ_{11} is a material constant, ρ_M is the membrane's density, and d_M is its thickness. At least a quarter of all “icy” animals possess a so-called tympanus muscle (Vedurmudi et al. 2020, Figs. 1–3) that pulls at the inferior process of the extracolumella, orthogonally to the eardrum's rim (Fig. 4b) and in this way can modify f_0 .

Let us now take a look at Fig. 7, which exhibits the effect of varying the tympanic-membrane tension T on both iTD (left) and iLD (right). Naively one might think that, by contracting the tympanus, T and thus f_0 increase so that the iTD plateau becomes wider, which seems to be advantageous to the animal; cf. Fig. 3. Certainly true but a price is to be paid in that the iTD height and, accordingly, the TDF = iTD/ITD decrease; see Fig. 7a. There is with $\pm 5\%$ error bar something like an equal-area (EA) rule saying that the total area under the TDF curve remains constant while varying f_0 .

As Fig. 7b shows, the iLD behavior is much more regular. The maximum remains practically constant and, as it behooves this maximum, it only shifts with f_0 . Done. An increase of up to 10% of the fundamental frequency is achievable with an applied tension of around 100 mN/m for the Varanus eardrum, a lifelike value. So for $f_0 = 400$ Hz, it is realistic to vary the fundamental frequency up to 440 Hz.

Summary and Conclusions

What have we gained through the novel notion of “internally coupled ears” (ICE)? On the sensory input side, the notion of ICE is a clean one as it describes precisely what the auditory geometry in the animal's head looks like and what, in conjunction with the material properties of the eardrums, the biophysical consequences for iTD and iLD are. Moreover, in the present context the animals are land-living vertebrates. It needs to be constantly borne in mind, though, that many insects also take advantage of ICE and that the notion of ICE – though not the name as such – dates back to the thirties of last century (van Hemmen et al. 2016, Sect. 2). In fact, it was the wart-biter, a bush cricket, that induced the scientific development

leading to what is now called ICE. Nevertheless, the geometry associated with the insects' anatomy is different. Second, the ensuing biological physics is merely based on the geometry of the interaural cavity coupling the two eardrums and their material properties, and nothing more than that. Third, geometric perturbation theory allows for both a systematic treatment and analytical evaluation of iTD and iLD in all desired orders of perturbation theory. Luckily, first order suffices in practically all circumstances.

What internally coupled ears (ICE) do is explained in section “[Performance of Internally Coupled Ears \(ICE\)](#),” notably Fig. 3. How they do this job as seen from a mathematical point of view can be found in section “[Mathematical Analysis and Explanation](#),” while a few enlightening specializations are described in section “[Extensions](#).” Neuronal information processing of the auditory system can be understood *only after* we have gained biophysical and, hence, computational insight into how the biological physics of auditory perception works. That is what has been done here for ICE.

Definition

Astrocytes are a predominant type of glia in the central nervous system. Although they do not generate electrical signals like neurons, they display a form of excitability characterized by fluctuations in their intracellular Ca^{2+} levels. These Ca^{2+} fluctuations show remarkable spatiotemporal complexity and diversity and further respond to various cellular stimuli. Modeling astrocyte Ca^{2+} dynamics is an essential step toward understanding their physiology and functions within neural circuits. This entry highlights the computational methods and approaches for modeling intracellular Ca^{2+} signals in astrocytes at the single cell level.

Detailed Description

Astrocytes are ubiquitously distributed throughout the central nervous system. Each astrocyte can display a complex morphology characterized by distinct compartments: the soma, primary branches and numerous fine processes, also referred to as branchlets. The latter account for around 75% of the surface of the astrocytic plasma membrane (Bindocci et al. 2017), providing astrocytes a spongiform appearance (see Fig. 1). Some of the fine processes, referred to as perisynaptic processes (PAPs), are in apposition to pre- and post-synaptic neurons, forming tripartite synapses, where they might modulate neuronal communication (see, e.g., Savtchouk and Volterra (2018) for a review). Some astrocytic ramifications, referred to as endfeet, wrap around blood vessels and are involved in neurovascular coupling.

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 1 Astrocytes are characterized by a complex morphology. Confocal image of a dye-filled hippocampal astrocyte, revealing its spongiform structure. Astrocytes also regulate neuronal excitability by maintaining ionic homeostasis (e.g., *K*⁺ buffering), uptaking neurotransmitters and moderating synaptogenesis (Verkhratsky and Nedergaard 2018).

Diversity of Astrocyte *Ca*²⁺ Signals

Cytosolic *Ca*²⁺ levels in astrocytes show ongoing fluctuations, both *in vitro* and *in vivo* (Verkhratsky and Nedergaard 2018). The amplitude, duration, and frequencies of these so-called *Ca*²⁺ signals/events vary depending on stimuli, such as adenosine triphosphate (ATP) and glutamate. As such,

those *Ca*²⁺ signals are crucial reporters of astrocyte function and are therefore a widely accepted form of astrocyte excitability. Astrocyte *Ca*²⁺ signals can result from diverse mechanisms such as *Ca*²⁺ influx from channels on the membrane of intracellular stores or on the plasma membrane, the spatial distribution of these channels, ATP signaling, and inter-cellular propagation of *Ca*²⁺ via gap junction coupling between astrocytes (Rizzuto and Pozzan 2006). A major pathway that triggers the release of *Ca*²⁺ in astrocytes is initiated by agonists binding to transmembrane G-protein-coupled receptors (GPCRs). This activates the synthesis of an intracellular second messenger, inositol 3-phosphate (*IP*₃). The *IP*₃ molecules bind to *IP*₃ receptor channels (IP3Rs), located on the endoplasmic reticulum (ER) membrane. Binding of *IP*₃ and *Ca*²⁺ to IP3Rs leads to the opening of IP3Rs, resulting in a *Ca*²⁺ influx from the ER into the cytosol. The resulting local increase in *Ca*²⁺ concentration, together with the *IP*₃ molecules, further activates more IP3R channels. This positive feedback loop, referred to as *Ca*²⁺-induced-*Ca*²⁺ release (CICR), can combine with the diffusion of *Ca*²⁺ and *IP*₃ to result in the propagation of *Ca*²⁺ events in the form of waves and of global (whole-cell) events. *Ca*²⁺ diffusion as well as pumps then restore basal cytosolic *Ca*²⁺ levels, thus terminating the signals.

The recent use of super-resolution microscopy and of highly sensitive genetically encoded *Ca*²⁺ indicators (GECIs) have revealed striking spatio-temporal diversity of astrocyte *Ca*²⁺ signals. Notably, there are remarkable differences between signals in the soma and in the peripheral processes (Srinivasan et al. 2015) (see Fig. 2). The latter account for around 80% of the total astrocytic *Ca*²⁺ activity *in vivo* (Bindocci et al. 2017). Those signals are localized in so-called microdomains and display faster kinetics and an order of magnitude smaller amplitudes compared to somatic *Ca*²⁺ signals. Around half of *Ca*²⁺ signals in fine processes persist in the absence of type 2 *IP*₃Rs. The *Ca*²⁺ pathways responsible for the other half of *Ca*²⁺ signals in branchlets are currently unknown and could involve type 1 or 3 *IP*₃Rs, *Ca*²⁺ channels on the plasma membrane or on the membrane of internal stores.

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 2 Diversity of astrocyte intracellular Ca^{2+} signals. *Left:* Astrocyte Ca^{2+} signals in a hippocampal astrocyte reported by GCaMP6f can be detected in discrete cellular compartments. The blue contour demarcates the approximate boundary of the

anatomical domain of the astrocyte. *Right:* The detected signals consist of large amplitude somatic oscillations (green), waves, largely in primary branches (red) and microdomains in fine processes (black traces, corresponding to yellow regions in the left image). (Adapted from Srinivasan et al. 2015 with permission)

A summary of the different spatial patterns of astrocytic Ca^{2+} signals is shown in Fig. 3, and their key features are listed below:

- **Global signals** (Fig. 3a) are IP_3R -dependent Ca^{2+} signals that propagate within the whole astrocyte (Bindocci et al. 2017).
- **Local waves** (Fig. 3b) are observed in branches and sporadically propagate bidirectionally to and from the soma. Ca^{2+} signals could also propagate through gap junction coupling between processes from the same cell (Rohlmann and Wolff 1996) (Fig. 3e), although this has not been reported so far. Note that gap junction coupling also allows for the propagation of intercellular waves, which will not be discussed here as this work focuses on Ca^{2+} signals at the single-cell level (see, e.g., Giaume and Venance 1998 for a review).
- **Spatially restricted microdomains** (Fig. 3c-d) are non-propagating signals characterized by distinct temporal properties (with a signal duration from the order of seconds (Srinivasan et al. 2015) to tens of seconds (Kanemaru et al. 2014)) and can be mediated by tetrodotoxin (TTX)-sensitive (neuronal activity-dependent)

and TTX-resistant mechanisms. Furthermore, these events can occur as IP_3R -independent events, notably in the absence of somatic Ca^{2+} signals (Srinivasan et al. 2015). Those signals are mostly observed in perisynaptic processes (Fig. 3c) or in blood vessel-associated endfeet (Fig. 3d) (Bindocci et al. 2017).

Taken together, the diversity of intracellular astrocyte Ca^{2+} signals concerns their spatial extent (from localized microdomains to whole-cell events), their time scales (order of seconds to tens of seconds), and, arguably, the mechanisms which trigger them. Their physiological roles are not well understood and constitute an active area of research (e.g., see review Verkhratsky and Nedergaard 2018). It is likely that the observed spatiotemporal variability of astrocyte Ca^{2+} signals is associated with the integration of signals in neural circuits coupled to local blood flow changes and metabolic processes to orchestrate integrative physiological functions.

Modeling Astrocyte Ca^{2+} Dynamics

The apparent diversity of intracellular astrocyte Ca^{2+} signals has led to the development of advanced computational tools and approaches to

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 3 Spatial diversity of intracellular Ca^{2+} signals in astrocytes. Ca^{2+} signals in a single astrocyte display various spatial forms. Some signals can propagate within the whole cell, forming a global event (a), propagate via regionalized Ca^{2+} waves (b), or be

localized at the vicinity of synapses (c), in endfeet (d), or might propagate to other processes of the same cell via gap junctions, although such an intracellular propagation via gap junction coupling has not been reported yet (e). PAP, perisynaptic astrocytic process

model astrocyte Ca^{2+} dynamics. A recent and significant advance corresponds to the development of spatially explicit multi-compartment models with realistic 3D morphologies in order to fully reproduce the spatiotemporal diversity of astrocyte Ca^{2+} signals (for a detailed review, see Manninen et al. 2018).

Approaches for Modeling Astrocyte Ca^{2+} Dynamics

In this section, the different approaches that can be used for simulating astrocyte Ca^{2+} signals are presented. Figure 4a summarizes those approaches, the approximations associated to it, as well as the resulting computational cost and accuracy. Briefly, modeling approaches can be

deterministic, i.e., in which all future states can be determined from the current state, or stochastic, i.e., considering each reaction as a probabilistic event. They can also be well-mixed, i.e., considering space as homogeneous and assuming that molecules are equally distributed within the system or spatially explicit. Those methods can be coupled within hybrid models (see, e.g., Winkelmann and Schütte 2017 for a review).

The first models of astrocyte Ca^{2+} signals were deterministic and well-mixed, formulated with ordinary differential equations (ODEs) (Manninen et al. 2018). Those models offered crucial insights on the qualitative and quantitative behaviors of the observed dynamics. However, the probabilistic molecular interactions in

reaction-diffusion systems often necessitate stochastic modeling approaches. Moreover, the spatial complexity of astrocyte morphology and Ca^{2+} signals (see Figs. 1 and 2) has led to the development of spatially explicit models. Figure 4b presents the different geometries that can be used in spatially explicit models of astrocyte Ca^{2+} signals. They can be either realistic or simplified, in 1–3 spatial dimensions. Those models are more realistic, increasing the accuracy of model predictions, however associated with an increased computational cost.

As fine astrocytic processes display complex geometries and have small volumes with low copy number of molecules, models of Ca^{2+} signals at this spatial scale are both stochastic and spatially explicit. The three main spatially explicit stochastic approaches used for simulating reaction-diffusion systems are presented in Fig. 4c, and a brief summary is also provided below. An excellent review of these approaches can be found in Burrage et al. (2011), and ► “Stochastic Simulators” and ► “Particle-Based Stochastic Simulators” detail the available spatially explicit stochastic simulators.

- **Particle-based (or particle-tracking or microscopic) models** (Fig 4c1)

The most straightforward stochastic spatially explicit approach consists of tracking the diffusive path of each individual molecule/ion (referred to as particle) within the spatial domain. Particles are characterized by their individual spheres of interaction/interaction radii. Second-order reactions occur depending on their rates when the reactants are within their interaction radii.

- **Voxel-based (or population-based or mesoscopic) models** (Fig 4c2)

As they are less computationally expensive than particle-based approaches, most intracellular Ca^{2+} models are implemented with the voxel-based stochastic approach. In this approach, the spatial domain is divided into small compartments (voxels) that are assumed well-mixed, and reactions can occur between reactants within the same voxel. Diffusion is modeled as a reaction in which the number of

molecules in the origin compartment is decreased by one, while the number of molecules in the neighboring compartment is increased by one. Accuracy and computational cost decrease with increasing sizes of compartments. (► “Stochastic Simulators”).

- **Hybrid models** (Fig 4c3)

Hybrid methods describe regions of particular interest such as the vicinity of Ca^{2+} channels with microscopic details, while other regions are simulated with a compartment-based approach. Those methods thus offer a trade-off between detailed modeling and computational cost.

Deterministic Models of Ca^{2+} Oscillations in Astrocytes

The early mathematical models of astrocyte Ca^{2+} signals primarily simulated the dynamics of IP_3 -dependent Ca^{2+} release from the ER. These largely consisted of deterministic models based on ODEs. The positive feedback loop of the CICR mechanism consisted of the rate of cytosolic Ca^{2+} influx as a sigmoid or Hill function of IP_3 concentration (see De Pittà et al. 2019 for a review). The termination of the resulting cytosolic Ca^{2+} increase resulted from the reuptake of Ca^{2+} into the ER via the activity of Smooth Endoplasmic Calcium ATPases (SERCA) pumps and from the exponential decay of IP_3 concentration. Together, the CICR and SERCA mechanisms formed the basis for oscillatory models of Ca^{2+} dynamics (see Fig. 5). Influx of Ca^{2+} via transmembrane voltage-gated Ca^{2+} channels was also incorporated using constant rates or realistic conductance-based (Hodgkin-Huxley) formalism.

$$\begin{aligned}\frac{d[Ca^{2+}]_c}{dt} &= J_{IP_3} + J_{leak} - J_{pump} + J_{in} - J_{out} \\ \frac{d[Ca^{2+}]_{ER}}{dt} &= \frac{1}{c_1} (J_{pump} - J_{leak} - J_{IP_3}) \\ \frac{d[IP_3]}{dt} &= I_{Ca} - I_{deg}\end{aligned}\quad (1)$$

To segregate the distal (peripheral) Ca^{2+} microdomains from somatic events, deterministic models have incorporated spatial partitioning

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 4 Approaches for modeling intracellular Ca^{2+} signals in astrocytes. (a) The different approaches available for modeling Ca^{2+} signals are presented from high accuracy/high computational cost associated with Brownian dynamics to less accurate but faster models of reactions based on ordinary differential equations. Note that hybrid methods are not represented in this schematic. (b) Depending on the biological question, the astrocytic geometry chosen for simulations can be in 3D (b1), either realistic, extracted from 3D reconstructions of experimental data (top), or simplified (bottom). The mesh in top B1 panel corresponds to a hippocampal astrocytic

process extracted and reconstructed from electron microscopy, provided by C. Cali, BESE Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia (Cali et al. 2016). Cytosolic volume is represented in green and ER volume in blue. 2D (b2) or 1D (b3) projections of 3D geometries can also be performed for computational efficiency, although it decreases the accuracy of the model. The top B3 panel was taken from Savtchenko et al. (2018), with permission. Panel C presents the main strategies for performing spatially explicit stochastic simulations: particle-based (c1), voxel-based (c2), and hybrid (c3) approaches

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 5 Classic IP_3 -dependent pathway incorporated in models of intracellular Ca^{2+} oscillations in astrocytes. (a) Plain black arrows correspond to Ca^{2+} fluxes. Dotted black arrows represent IP_3 formation, via Ca^{2+} -dependent PLC activity, and

degradation. Red dotted arrows represent the activation of certain molecules, such as IP_3R and PLC, by IP_3 or Ca^{2+} . (b) A simulated trace of intracellular $[Ca^{2+}]$, displaying $[Ca^{2+}]$ oscillations, based on the model from Lavrentovich and Hemkin (2008)

based on realistic astrocyte morphology. The Brazhe et al. (2018) model, for instance, considered the z-projection of the 3D morphology of a rodent hippocampal astrocyte (see Fig. 6a). Following a spatial discretization, the internal compartments were labeled as belonging either to the perimembrane region (type I) or the deep region (type II), depending on their distance from plasma membrane. In type I regions, glutamate binding at synapses can promote IP_3 production and Ca^{2+} influx. Local Ca^{2+} increases and concomitant IP_3 production were posited to spatially diffuse into the neighboring type II region. The type II region consisted of the classic IP_3R -activated Ca^{2+} release from the ER and the IP_3 - Ca^{2+} CICR, together capable of generating global waves via a positive feedback loop. The two regions were assumed to be coupled by a diffusive Ca^{2+} flux (J_{diff}) and an IP_3 flux (I_{diff}) for which the diffusion coefficients were estimated based on the cell morphology. This approach offers insight into a mechanism by which synaptically driven peripheral Ca^{2+} fluctuations might contribute to the integration and initiation of global events (see Fig. 6b). Additionally, modeling the synaptic input with a noise term (e.g., Poisson process) generated uncorrelated peripheral events representative of realistic Ca^{2+} microdomains. An advantage of this model is that it can be used to study signal propagation within ER-free branchlets.

ODEs for the perimembrane, glutamate uptake-dependent region from the Brazhe et al. (2018) (type I region; see Fig. 6a, blue):

$$\begin{aligned}\frac{d[Ca^{2+}]_c}{dt} &= J_{in} + J_{glu} - J_{out} + J_{diff} \\ \frac{d[Glu]}{dt} &= \frac{[Glu]^* - [Glu]}{\tau_{Glu}} + \xi_p + G_{diff} \\ \frac{d[IP_3]}{dt} &= I_{Glu} + I_{Ca} - I_{deg} + I_{diff}\end{aligned}\quad (2)$$

ODEs for the deep, IP_3R activation-dependent region from the Brazhe et al. model.

Brazhe et al. (2018) (type II region; see Fig. 6a, pink):

$$\begin{aligned}\frac{d[Ca^{2+}]_c}{dt} &= J_{IP_3} + J_{leak} - J_{pump} + J_{diff} \\ \frac{d[Ca^{2+}]_{ER}}{dt} &= -\frac{1}{c_1} (J_{IP_3} + J_{leak} - J_{pump}) \\ \frac{d[IP_3]}{dt} &= I_{diff} - I_{deg}\end{aligned}\quad (3)$$

Recently, detailed 3D reconstructions of astrocyte morphology have been used to generate realistic spatially explicit compartmental models of astrocytes combined with deterministic formulation of Ca^{2+} fluxes within compartments (Savtchenko et al. 2018) (see Fig. 7a). The spatial discretization has captured the

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 6 Spatially partitioned oscillators. (a) 3D reconstruction from an astrocyte imaged with confocal fluorescent microscopy was projected in 2D and then divided into two types of compartments, perimembrane (blue) or deeper regions (pink), that were then spatially discretized. The ODEs that describe Ca^{2+} and IP_3 dynamics in both compartments are

presented in Eqs. 2 and 3. Terms are described in Table 1. (b1) Image displaying the different regions of interest (ROIs) within the model (numbered 1-12). spatiotemporal dynamics of diverse Ca^{2+} signals measured experimentally, supporting the usefulness of this approach to further investigate astrocyte physiology in health and disease. However, molecular reactions in small discrete compartments such as microdomains in fine astrocytic processes are inherently probabilistic events. Stochastic modeling approaches offer an attractive alternative when a detailed description of Ca^{2+} signals in microdomains is needed.

Stochastic Approaches for Modeling Intracellular Astrocyte Ca^{2+} Signals
Molecular interactions in spatially restricted compartments such as thin astrocytic processes, which are believed to be the site of neuron-astrocyte communication, occur when molecules are in low copy numbers. Stochastic approaches can describe the associated heterogeneous reaction rates and the inherent stochasticity of biochemical reactions so that they are being used to model astrocyte Ca^{2+} signals in fine processes. Recently,

some astrocyte models have started to incorporate noise using hybrid approaches in order to better simulate stochastic components of Ca^{2+} dynamics at the subcellular level. For example, Cresswell-Clay et al. (2018) have developed a whole-cell model of a single astrocyte consisting in a soma with five main branches, all containing ER. Ca^{2+} signals were implemented as a stochastic influx. Their results suggest that both cellular geometry (e.g., somatic volume) and the velocity of diffusing molecules influence the coupling and nature of the Ca^{2+} signals in response to neuronal stimulation. Interestingly, simulations also revealed

complex spatiotemporal characteristics of Ca^{2+} depletion in the somatic ER in response to Ca^{2+} signals in processes, due to intra-ER Ca^{2+} diffusion. For reviews on stochastic models of Ca^{2+} signals, see, e.g., Rüdiger and Shuai (2019) and Manninen et al. (2018) for astrocytes.

As the nanoscale geometry of astrocytic processes can reduce diffusion coefficients due to the tortuosity of the compartment, accurate description of the local variations of the number of Ca^{2+} ions requires spatially explicit models. Spatially explicit stochastic models of Ca^{2+} signaling were first developed to

Intracellular Calcium Signals in Astrocytes, Computational Modeling of, Fig. 8 Simulations of a fully stochastic voxel-based model reproduce experimental measurements of Ca^{2+} signals in fine astrocytic processes. (a1) Spontaneous local Ca^{2+} signals were measured in GCaMP6s-expressing astrocytes from hippocampal organotypic culture. (a2) Magnification of panel A1, presenting the 5 regions of interest (1–5) from which Ca^{2+} traces have been recorded (a3). (b) Geometry used in simulations that represents a simplified region of interest, i.e., a fine process. It consists in a cylinder that is 1 μm long

and 200 nm in diameter. (c) Representative simulations of Ca^{2+} dynamics within the fine process geometry presented in panel B, with the different implementations of the model: “No-GCaMP” (no buffers are present in the model; free Ca^{2+} concentration is monitored), “GCaMP” (GCaMP Ca^{2+} indicators are added to the model; GCaMP-Ca concentration is monitored), and “GC + Buf” (GCaMP and endogenous Ca^{2+} buffers are added to the model; GCaMP-Ca concentration is monitored). (Adapted from Denizot et al. 2019 with permission, article with Creative Commons License)

reproduce local Ca^{2+} dynamics in neural dendrites, characterized by small volumes and low numbers of Ca^{2+} ions (5–6 ions in a half- μm diameter dendritic spine). These studies have demonstrated the influence of dendritic morphology (e.g., dendritic diameter) on the spatiotemporal characteristics of Ca^{2+} signals and their compartmentalization (see CrossRef: [▶ “Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis”](#)). These models highlighted the influence of diffusive noise on intracellular signaling networks, suggesting that noise is an important factor to be considered for accurate description of molecular interactions.

A novel spatially explicit fully stochastic model of Ca^{2+} signals in astrocytes has been proposed by Denizot et al. (2019). The two types of spatially explicit stochastic implementations in the study were:

- A 2D particle-based model to explore the effects of model parameters on the range of Ca^{2+} dynamics that the model can display.
- A 3D voxel-based model in which the geometry of the reaction volume mimicking an astrocytic process consisted of a cylinder of length $L_{\text{astro}} = 1 \mu\text{m}$ and radius $R_{\text{astro}} = 0.1 \mu\text{m}$ (Fig. 8b). Several variations of this model have been implemented to investigate the

effects of multiple mechanisms on astrocyte Ca^{2+} microdomains including (1) clustering of IP₃R channels, (2) endogenous buffers, and (3) GCaMPs (ultrasensitive genetically encoded Ca^{2+} indicators that fluoresce when bound to Ca^{2+}).

Ca^{2+} dynamics in simulations of the model were compared to signals that were measured experimentally in fine processes of hippocampal astrocytes (Fig. 8a). The model successfully reproduced Ca^{2+} peak amplitude, frequency, and duration measured in fine processes and is therefore a valuable tool for investigating intracellular astrocytic Ca^{2+} signals at the subcellular level. Key insights from this model highlight the importance of the spatial distribution of various Ca^{2+} sources within an astrocyte and suggest that local variations of Ca^{2+} indicators might contribute to the spatiotemporal diversity of astrocytic Ca^{2+} excitability.

Conclusion

Understanding astrocytic Ca^{2+} signaling is at the forefront of neuroscience research. The diversity of astrocyte Ca^{2+} excitability may relay spatiotemporally complex code which yet remains to be decoded. Computational modeling of astrocyte physiology and Ca^{2+} dynamics is an essential step toward unraveling the functions of astrocytes in neural circuits. Recent conceptual advances in experimental work have highlighted the spatiotemporal diversity of Ca^{2+} signals at the single-cell level. Parallel advances in tools and methods for modeling astrocytes are beginning to provide novel insights into their physiology. Future work combining neuron-astrocyte models may thus enhance our understanding of the role of astrocytes in neural signal processing in health and disease.

Definition

Intraspinal stimulation or microstimulation generally refers to electrical activation of the spinal cord through delivery of electrical current directly into the spinal tissue using microwire electrodes implanted into the white or grey matter of the cord. The term may also be applied for activation of the spinal tissue through iontophoresis (Saltiel et al. 1998) or optogenetics method (Alilain and

Silver 2009). The range of applications includes lower and upper limb movements, bladder and bowel function, and respiration.

Detailed Description

The Spinal Solution to Multi-joint Movement Control and Other Problems

As evidenced in other sections of this encyclopedia (► [“Vertebrate Pattern Generation: Overview”](#)), part of the substantial repertoire of movements observed in vertebrates is programmed at the level of the spinal cord and can function after injury to more rostral levels. Thus, “One of the major challenges facing clinical neurobiologists is how to exploit the untapped reserves of coordinated movement contained in the spinal cord circuits of patients with a functionally isolated spinal cord” (Burke 1992). Selective activation of these spinal cord circuits could lead to enhancements in neuroprostheses for the restoration of movements. While electrical stimulation of paralyzed muscles has been used by various research groups to restore function to the paralyzed neuromuscular system (grasp/release (Handa et al. 1992; Keith et al. 1996)), wrist flexion/extension (Lemay and Crago 1997; Nathan and Ohry 1990), elbow (Grill and Peckham 1998), and arm control (Hincapie et al. 2008; Smith et al. 1996) in individuals with tetraplegia, as well as standing/walking functions in paraplegics (Andrews et al. 1988; Kralj et al. 1983; Marsolais et al. 1991), issues arise as the number of joints to be controlled increases. For multi-joint movements, the number of muscles to be stimulated increases and the task of coordinating those muscles’ activation is greatly complicated by (1) muscle function redundancy, (2) interaction between limb segments through multi-articular muscles and dynamic effects, and (3) other voluntary or reflex actions (Chizeck et al. 1988). Unassisted Functional Neuromuscular Stimulation (FNS) walking requires as many as 48 channels of stimulation and an elaborate tuning of the activation sequence (Marsolais et al. 1991).

The problems posed by multi-joint control are easily addressed by the spinal cord which can

autonomously produce complex movements such as scratching to a target or locomotion. Part of the solution involves modular use of the musculature, as multi-muscle building blocks or primitives that are reused for various movements. This biological solution provides opportunities for stimulation pattern completion strategies based on available voluntary muscles in conventional functional electrical stimulation (FES) as explored by Kirsch and colleagues (Hincapie and Kirsch 2009) and for movement control using intraspinal microstimulation (ISMS). Stimulation of higher-order spinal neurons provides a way of coordinating the activation of the skeletal muscles by recruiting modules or primitives that can be described as feedforward controllers that alleviate the coordination and delay problems of the slow sensory feedback by using the neural circuitry present below the level of the cord injury (Giszter et al. 2000). Presence of low-level spinal reflexes then provides feedback mechanisms that may be able to compensate for fatigue and adapt to changing conditions.

In addition to the circuitry responsible for movements, interneurons involved in bladder (de Groat and Wickens 2013) and respiration (Lane et al. 2009) control are also contained within the cord’s grey matter and can be activated via electrical stimulation or other methodologies as described below.

Intraspinal Stimulation for Movement Applications

Work on intraspinal microstimulation has focused on direct activation of the motoneuronal pools using fine wire microelectrode implanted deep into the lateral ventral horns (Mushahwar and Horch 2000a, b) or into activation of higher-order neurons by stimulation delivered into the intermediate grey matter (Barthelemy et al. 2006; Giszter et al. 1993; Lemay and Grill 2004; Tai 2003; Tresch and Bizzi 1999), or even dorsal columns (Barthelemy et al. 2006). The small volume and proximity between motor pools within the spinal cord allow recruitment of a larger portion of the muscle than traditional intramuscular

electrodes. In addition, the number of electrodes is possibly reduced (proximity of synergistic motor pools to one another would allow coactivation of synergistic muscles), and the electrodes are in a location that suffers less strain, diminishing the risk of electrode breakage (Mushahwar and Horch 1997), although the risk of tissue damage is higher as the electrode is implanted directly into the spinal tissue instead of sitting extradurally to the cord as with epidural stimulation. As demonstrated by modeling (see ► [“Finite Element Modeling for Extracellular Stimulation”](#) in this encyclopedia) and experimental studies (Gustafsson and Jankowska 1976), neuronal activation with intraspinal microstimulation is mostly through transynaptic mechanisms (Gaunt et al. 2006), and recruited fibers of passage lead to a spread of activation to higher-order neurons responsible for the stereotype movements programmed at the level of the interneuronal circuitry. Thus, both approaches (motoneuronal pool or intermediate grey targeting) lead to activation of spinal elements spreading across multiple laminae and segments.

With electrodes implanted in the dorsal, intermediate, or ventral grey of the lumbosacral enlargement, flexion or extension whole limb movement can be obtained through electrical activation with stimuli train in intact or spinal animals (Barthelemy et al. 2006; Boyce and Lemay 2009; Giszter et al. 1993; Saigal et al. 2004; Tresch and Bizzi 1999). Tonic stimulation may even evoke locomotor activity with some reports suggesting that dorsal rostral sites (in dorsal column or dorsal horn around L3/L4 in spinal cats) are more efficacious (Barthelemy et al. 2006), while others report that stimulation of ventral caudal sites (intermediate grey of the L7/S1 region) is more prone to produce bilateral alternating movements in the hindlimb (Guevremont et al. 2006). Flexion responses are typically produced by stimulation in the dorsal horn and may be related to activation of the flexor withdrawal reflex since nociceptive afferent input terminates in the dorsal horns (Barthelemy et al. 2006; Boyce and Lemay 2009; Tresch and Bizzi 1999). Stimulation in more ventral sites tends to produce a greater mix of responses (flexion and extension) (Lemay and

Grill 2004), although a definite somatotopical map of the response type obtained based on electrode location is not apparent.

The responses to stimulation are typically measured either as movements (Barthelemy et al. 2006; Guevremont et al. 2006; Tai 2003) or as isometric force patterns representing the direction and magnitude of the forces produced by activation of a spinal site throughout the limb's workspace (Giszter et al. 1993; Lemay and Grill 2004; Tresch and Bizzi 1999). Forces are plotted as vectors through the workspace with the length of the vector representing force magnitude and vector orientation representing the direction of the force. The responses (movements or forces) obtained with stimulation are stereotypical and similar across individual animals. Across species the responses typically include a pattern of isometric force that would drive the limb toward the body (flexion withdrawal type of response), in caudal or rostral extension, and in some cases in rostral flexion, if free to move. The forces generated and measured under isometric conditions can be generalized to viscoelastic forces incorporating muscle properties for use under dynamic conditions. Indeed computational models of limb movements support this generalization (Giszter and Kargo 2001), and the control theory analysis of the motions produced shows that the force patterns may represent optimal ways of exciting limb dynamics based on analysis of limb mechanics (Berniker et al. 2009). Kinematics measurements of the motion produced by the force pattern measured under isometric conditions (Giszter et al. in the frog (Giszter et al. 1993) and Lemay et al. in the cat (Lemay et al. 2009)) demonstrated that the isometric force patterns were good predictors of the movements obtained by stimulation of the spinal site. The force patterns summate during coactivation of spinal sites, and thus, they can be used as building blocks of movement (Mussa-Ivaldi 1997). The summation property may be limited to the spinal condition (although see results for stimulation in cervical enlargement in the monkey below) as only winner take all (response from one stimulated site dominating during co-stimulation) was observed in decerebrate spinal intact cats (Lemay et al. 2009).

Evidence also suggests that circuits for reaching movements can be activated by intraspinal microstimulation as shown in non-human primates (Moritz et al. 2007; Zimmermann et al. 2011). Movements involving the shoulder, elbow, wrist, and hand were produced through activation of the grey matter or fiber tracts with trains of 3–20 stimulus pulses. Movements were produced through coactivation of multiple muscles, and sites producing arm or hand motions could be simultaneously activated to enable grasp, transport, and release of an object (Zimmermann et al. 2011).

Control of Bladder Function

Intraspinal microstimulation has also been used to produce voiding in spinal cord-injured individuals. Early work by Nashold and colleagues (1981) produced voiding in about 60 % of patients implanted with bilateral penetrating electrode into the conus medullaris. More recent detailed mapping of the sacral segments in cats showed the possibility of generating bladder pressures without increases in urethral pressure by microstimulation (~100 μ A) in the intermediolateral region (lamina VII) and the lateral ventral horn (Lamina VII) of the S1 and S2 sacral segments. Similar effects were observed for stimulation around the central canal (Lamina X) (Grill et al. 1999). Stimulation in those regions was thus effective at producing voiding. On the other hand stimulation in the ventrolateral ventral horn (laminae IX level) produced a concomitant increase in urethral pressure preventing effective voiding (Grill et al. 1999). Stimulation in dorsal horns (laminae II–IV) produced large increases in urethral pressure with minimal increases in bladder pressure; thus, those sites were better for ensuring continence (Tai et al. 2004). Mapping results obtained in spinal intact animals studied under anesthesia were generally similar in chronic spinal animals (Pikov et al. 2007). To date, the voiding obtained with intraspinal microstimulation has not been shown to be consistently superior to the one obtained with anterior sacral root stimulation (and dorsal rhizotomy) (see

► “Methodologies for the Restoration of Bladder and Bowel Functions” in this encyclopedia), and some authors have argued that the methodology is not worth the increased implantation risks (Gaunt and Prochazka 2006).

Control of Respiration

Recent evidence suggests that intraspinal stimulation may also be used to activate/potentiate respiratory spinal circuits, although in this case activation is through light delivery. Through viral gene delivery, it is possible to express Channelrhodopsin-2, a light-activated cation channel, in mammalian neurons. These neurons can then be depolarized by photostimulation to produce action potentials. In a cervical hemisection, it has been shown that phrenic activity ipsilateral to the lesion can be induced with photostimulation and that the activity is maintained for periods after the cessation of light, as it is hypothesized that crossed descending input to the phrenic nucleus is potentiated by the light-induced depolarization (Alilain et al. 2008). The technique could potentially be used in full transection to activate the phrenic nucleus via activation of the phrenic motoneurons or spinal respiratory circuit interneurons.

Future Directions

Examples in locomotor (Boyce and Lemay 2009) and autonomic (Pikov et al. 2007) systems indicate that the responses to intraspinal microstimulation are similar after chronic spinal cord injury although the relative proportions of each response types may alter with rehabilitation (Boyce and Lemay 2009). This suggests that the spinal circuits of interest are preserved when disconnected from supraspinal centers and can still be recruited to restore various functions. The spinal circuitry and its potential topological organization are still rather poorly understood although various efforts are underway to delineate the spinal circuitry responsible for locomotion, micturition, and respiration and their topological

organization (► [“Vertebrate Pattern Generation: Overview”](#)). Clinical applications in humans await development of electrode with mechanical properties suitable for chronic implantation into a soft spinal tissue that is subjected to much greater displacements than the ones observed in the cortex (see ► [“Braided Electrodes”](#) in this encyclopedia).

Inverse Problems in Neural Population Models

Roland Potthast
Department of Mathematics, University of
Reading, Reading, UK

Definition

Inverse problems are usually based on some *direct* or *forward model*, where the inversion aims to determine either parameter distributions of the model or states of the dynamics. The application and development of inverse techniques to neural population models will be discussed here with a

focus on neural field theory. The goal is the construction and reconstruction of neural connectivity and parameters of neural activity such as the local activation of pulses or spike trains.

Detailed Description

Neural Field Models such as the Cowan-Wilson Model (Wilson and Cowan 1972, 1973; Nunez 1974) or the Amari Neural Field Model (cf. Amari 1975, 1977) establish a field-theoretic approach to the dynamics of neural activity in the brain. The models use excitations and inhibitions over some distance as an effective model of mixed inhibitory and excitatory neurons with typical cortical connectivities, for example, by a simple dynamical equation for the voltage or activity $u(x, t)$ of the form

$$\begin{aligned} \tau \frac{\partial u}{\partial t}(x, t) = & -u(x, t) \\ & + \int_B w(x, y) f(u(y, t) - D(x, y)/v) dy, \end{aligned} \quad (1)$$

$x \in B, t \geq 0$, where initial conditions $u(x, 0) = u_0(x)$, $x \in B$ are given. Here, B is our *brain*, i.e., some domain where the neural activity takes place; f is the local *activation function* or *firing rate function*; w is the *connectivity function* which models the strength of the connectivity or signal propagation from $y \in B$ to the point x ; D is the length of the fiber from x to y ; and v is the propagation speed of the signal.

Inverse problems for such models aim for the determination of either the connectivity kernel $w(x, y)$ or both the connectivity kernel w and parameters of the activation function f . In addition to w and f , inverse neural field problems can also aim to determine the parameter distribution of τ , where either τ is a scalar constant or $\tau = \tau(x)$ is a distributed function.

As a generic problem, for the case $v = \infty$ (such that we can drop the delay term in Eq. 1) and where τ and f are known, assume that the function $u(x, t)$ in Eq. 1 is measured for $x \in B$ and $t \geq 0$. The task to determine $w(x, y)$ from these

data is known as *full field neural inverse problem* (Potthast and beim Graben 2009a,b). Using

$$\begin{aligned} \psi(x, t) := & \tau \frac{\partial u}{\partial t}(x, t) \\ & + u(x, t), \varphi(y, t) := f(u(y, t)) \end{aligned} \quad (2)$$

for $x, y \in B, t \geq 0$, the inverse problem is transformed into a family of *integral equations*

$$\psi(x, t) = \int_B \varphi(y, t) w(x, y) dy, t \geq 0, \quad (3)$$

$x \in B$ (cf. Coombes et al. (2013)). For each $x \in B$, Eq. 3 is an independent integral equation of the *first kind*. It is well known (cf. Kress (1989), Kirsch (1996)) that integral equations of the first kind with continuous or weakly continuous kernel are *ill-posed*, i.e., the calculation of the solution $w(x, \cdot)$ cannot depend stably on the right-hand side. An equation is called *ill-posed* if one or several of the demands of (I) *existence* of a solution for each right-hand side, (II) *uniqueness* of solutions, and (III) *stable dependence* of the solution on the data are violated.

Regularization methods (cf. Kress (1989)) replace the unstable inverse A^{-1} of the operator

$$(Ag)(t) := \int_B \varphi(y, t) g(y) dy, t \in [0, \infty], \quad (4)$$

by a family of bounded operators R_α , such that

$$R_\alpha f^* \rightarrow g^*, \quad \alpha \rightarrow 0, \quad (5)$$

where $Ag^* = f^*$, i.e., g^* is the true solution with true right-hand side f^* . Regularization for the neural field problem as, for example, by *Tikhonov regularization*

$$R_\alpha := (\alpha I + A^* A)^{-1} A^* \quad (6)$$

is worked out in (Potthast and beim Graben 2009a,b); methods for reducing the ill-posedness by *dimensional reduction* have been suggested in (Potthast et al. 2009). The authors also study *transformations* of neural space such that inverse neural problems can be reduced in dimensionality and made independent of the dimension of the

actual neural space in which the task is imbedded. For example, an excitation problem in a space of 10^4 neurons can be reduced to a one-dimensional problem, even though it is distributed over the full original neural space.

Inverse problems for neural field theory have been applied to modeling processes of language generation and language parsing in *dynamic cognitive modeling* (beim Graben and Potthast 2009). The implementation of a *Turing computer* in the framework of neural field architectures has been based on inverse problems techniques in (beim Graben and Potthast 2012b, 2013).

Inverse Problems in NFT and Dynamic Causal Modeling

Dynamic causal modeling was originally developed by (Friston et al. 2003, 2006) to estimate the causal coupling between brain regions from the activity observed by functional magnetic resonance imaging (fMRI) measurements.

More generally, the aim of *dynamic causal modeling* (DCM) (Friston et al. 2006; Friston 2009; Penny et al. 2004; Kiebel et al. 2008) is to determine the causal structure within distributed dynamical systems. In contrast to *inverse problems for dynamical systems*, where the goal is to determine the underlying unknown parameters of the system, *dynamic causal modeling* parameterizes the conditional dependencies by an *effective connectivity*, where DCM employs a simple deterministic model based on ordinary differential equations of neural dynamics in a network or graph.

In this sense, *dynamic causal modeling* can be seen to employ *inverse problems* techniques within a specific setup and application area.

Inverse Problems and Bayes' Theory

Bayes' theory (Berger 1985) estimates some conditional probability distribution $\pi(x|y)$, i.e., the probability of x under the condition of y , when a prior distribution $\pi(x)$ and the conditional distribution $\pi(y|x)$ of y under the condition x are given, using *Bayes' formula*

$$\pi(x|y) = \frac{\pi(x)\pi(y|x)}{\pi(y)} \quad (7)$$

If some prior distribution $\pi(w)$ for the *neural connectivity* w is known, measurements of the *activity fields* u with dynamics Eq. 1 with error distribution $\pi(u|w)$ can be employed to calculate the posterior *neural kernel distribution* $\pi(w|u)$ by Eq. 7, where $\pi(u)$ is determined by the standard probabilistic *norming condition* $\int \pi(w|u) = 1$.

As shown in Freitag and Potthast, Kaipio and Somersalo, for *Gaussian distributions*, the calculation of the *mean* or *maximum likelihood estimator* MAP is identical to the regularization approach Eq. 6. In this case, *regularization theory* of inverse problems and *Bayes' estimation* coincide. The regularization parameter is determined by the covariances of the distribution under consideration.

Advantages of the Approach

Inverse problems appear naturally in many parts of cognitive neuroscience to estimate or determine the connectivity in the brain or parameters of equations which are used to simulate the chemical, physiological, or electrical activity. Thus, the inverse problems approach to neural field theory is a natural and universal approach, which is needed for any system simulating real data.

Limitations

Inverse problems in neural population models are usually strongly underdetermined. It is almost impossible to capture the full complex dynamics which takes place in real systems from limited number and resolution of measurements. Thus, it is common to work with reduced dynamics and particular model systems. But this also strongly limits their applicability in a realistic framework.

Inward Rectifier Potassium Channels

Yann Le Franc

Theoretical Neurobiology and Neuroengineering,
University of Antwerp, Wilrijk, Belgium

Synonyms

[Anomalous rectifier potassium channels](#); [GIRK channels](#); [K-ATP channels](#); [Kir channels](#)

Definition

Inward rectifier potassium channels, also called Kir channels are potassium channels which, on the contrary of the other potassium channels, let

little potassium ions flow outside of the cell and allow a large inflow of potassium ions inside the cells. In other words, inward rectifier currents present a reduced outward current at membrane potential above the potassium reversal potential and large inward current for membrane potential below the potassium reversal potential.

Detailed Description

First described in skeletal muscle, these channels have been identified in several other cell types: cardiac myocytes, blood cells, osteoclasts, endothelial cells, epithelial cells, oocytes, neurons, and glial cells (for review, see Hibino et al. 2010).

The inward rectifier potassium channels are part of a heterogeneous family of potassium channels named Kir m.n or KCNJ.x. This family can be categorized into four subclasses: transport channels (Kir1.n, Kir4.n, Kir5.n, Kir7.n), regular Kir channels (Kir2.n), G protein-gated channels (Kir3.n), and ATP-sensitive channels (Kir6.n) (Hibino et al. 2010).

These particular channels are not voltage-gated channels due to the lack of S4 voltage sensor, conserved in the different families of voltage-gated channels (Hibino et al. 2010). Despite this lack of voltage dependence, the current flowing through the inward rectifying channels is asymmetric with large inward current and small outward current. This asymmetry is due to the blockade of the permeant pore by intracellular divalent ions (Mg^{2+})/polyamines for depolarized potential.

In experiments realized with various extracellular potassium concentrations, the current-voltage relationship remains asymmetric and is shifted to the new potassium reversal potential (see Fig. 5.14, p. 152, Hille 2001). Similar experiments realized with various intracellular potassium concentrations do not show a similar phenomenon. This demonstrates that inward rectifier channel current activation depends on the difference between the membrane voltage V_m and the impact of extracellular potassium concentration on the potassium reversal potential E_{K+} , given by the quantity $R \cdot T \cdot \ln[K]_o$ (Hille 2001).

How to Model These Channels?

The Kir current-voltage relationship is asymmetric with large inward current for potentials more hyperpolarized than the potassium reversal potential (E_{K+}) and small outward current for potentials more depolarized than E_{K+} (see Fig. 1a, b). This asymmetry can be approximated by Hodgkin and Huxley equations, considering that the activation of the channels is maximal at potentials below E_{K+} and decreasing toward zero for potential more depolarized than E_{K+} (see Fig. 1c).

Several models used this assumption to account for the effects of these particular channels in medium spiny neurons (Gruber et al. 2003; Wolf et al. 2005) or in deep dorsal horn neurons of the spinal cord (Le Franc and Le Masson 2010).

In these different cellular models, the current was modeled as a classical Hodgkin and Huxley current, given by the following equation:

$$i_{Kir} = \bar{g}_{Kir} * m(V) * (V_m - E_{K+})$$

where i_{Kir} is the inward rectifier current, $\bar{g}_{Kir}$ is the maximal conductance of the channels, $m(V)$ is the gating variable representing the voltage-dependent channel activation, V_m is the cell membrane potential, and E_{K+} is the reversal potential of the potassium given by the Nernst equation (see Nernst equation).

The variation of the activation is given by the following equation:

$$\frac{dm}{dt} = \frac{m_{\infty} - m}{\tau_{Kir}}$$

The steady-state voltage-dependent activation of the channel m_{∞} can be represented by a simple sigmoidal function:

$$m_{\infty}(V) = \frac{1}{1 + \exp((V_{tn} - V_{half})/slope)}$$

Common values for the slope are around 10 mV (13 mV in Wolf et al. 2005; 10 mV in Le Franc and Le Masson 2010; 11 mV in Gruber et al. 2003), while values for the half-activation can be

Inward Rectifier Potassium Channels, Fig. 1 Kir 2.x model. Simulated Kir current based on Wolf (Wolf et al. 2005; ModelDB accession number: 112834). Simulation was run on NEURON 7.2. The current has been inserted in a 10-by-10 μm compartment. The potassium reversal potential E_{K^+} has been set to -90 mV, the Kir maximal

conductance to $150 \mu\text{S}/\text{cm}^2$. The simulation time step was 0.025 ms. $E_{\text{K}^+} = -90$. (a) The simulated Kir current (top) was held at -90 mV and V_m was increased in 20 mV steps (bottom) from -150 mV to $+10$ mV for 800 ms. (b) Steady-state I/V relation for the simulated Kir current. (c) Voltage dependence of the steady-state activation $m_\infty(V)$

more variable (-52 mV in Wolf et al. 2005; -111 mV in Gruber et al. 2003; -65 mV in Le Franc and Le Masson 2010).

This particular model can be used to represent Kir2.x channels (Gruber et al. 2003; Wolf et al. 2005) G protein-gated inward rectifying potassium channels (Kir3.x; Le Franc and Le Masson 2010). However, a recent model has been proposed to account for the activation of Kir current by GABA_B (Sanders et al. 2013).

Functions in the Nervous System

In the nervous system, the different Kir channel types share the same function in physiological conditions: reducing the neuronal excitability by bringing the resting potential near E_{K^+} .

Due to their activation by neuromodulators, the Kir3.x or GIRK (G protein-gated inward rectifier K⁺) channels have been shown to play a crucial role in the nervous system in regulating neuronal excitability at different levels: neuronal self-inhibition, neuron-to-neuron inhibition, or network-level inhibition (for more details, see Lüscher and Slesinger 2010).

Their regulation by metabotropic receptors (glutamate and GABA) has been proposed as a mechanism for bistability contributing to persistent firing in working memory (Sanders et al. 2013) and pain processing (Derjean et al. 2003).

With the large diversity of regulations (Wang et al. 2011), these channels are implicated in multiple disease states including neurological diseases such as epilepsy, Parkinson's disease, Down's syndrome, and drug addiction (Lüscher and Slesinger 2010).

Ionotropic Receptors Dynamics, Conductance Models

Matthias H. Hennig

Institute for Adaptive and Neural Computation,
School of Informatics, University of Edinburgh,
Edinburgh, UK

Definition

Ionotropic receptors are an ion channel that opens upon binding of ligand molecules such as neurotransmitters. In addition, receptors may transition into desensitized, nonconducting states. These state transitions can be described with kinetic models, which replicate the time course of the resulting gating and corresponding conductance changes. Such models are particularly useful to simulate the postsynaptic conductance caused by neurotransmitter release during synaptic transmission.

Detailed Description

The temporal dynamics of synaptic transmission strongly depends on the kinetics of postsynaptic neurotransmitter receptors. Binding of transmitter molecules to ionotropic receptors causes a conformational change of the protein that opens an ion channel, which in turn gives rise to a membrane conductance change (Hille 2001). The observation of discrete open and closed states in single-channel recordings has supported the notion that a receptor protein functions by traversing through a succession of conformational state changes (Neher 1992). This motivates the use of kinetic models to describe receptor dynamics. In addition to opening and closing, receptors can also enter long-lived desensitized states, where the ligand is bound but the channel remains closed (Jones and Westbrook 1996).

Alpha Function

A very simple model for the time course of the synaptic conductance change following a presynaptic action potential is the alpha function, first introduced by Rall (1967):

$$g_{\text{syn}}(t) = \frac{t - t_0}{\tau} \exp\left(-\frac{t - t_0}{\tau}\right); t > t_0 \quad (1)$$

This model describes the postsynaptic conductance $g_{\text{syn}}(t)$ caused by a presynaptic action potential at time t_0 . The single parameter τ determines both the peak time at $t_p = t_0 + \tau$ and the time constant of the exponential decay (Fig. 1a). The parameter can be adjusted to reflect the differences between synapses, such as fast AMPA/kainate receptors ($\tau < 1$ ms) or slower NMDA receptors ($\tau \approx 40$ ms).

This model can be derived as a special case of a second-order kinetic model (see Destexhe et al. 1994, for details), but there is no clear biological interpretation of the parameter. In addition, it fails to reproduce the relatively fast rise times of

synaptic conductances; therefore, extensions such as models with two exponential functions have been proposed (Gerstner and Kistler 2002). In practice even simpler models such as a linear first-order reaction are often used for computational efficacy.

Markov Models

A more comprehensive approach to modelling ionotropic receptors are finite-state models (Destexhe et al. 1994). This involves listing all possible states of the protein as well as the allowed transitions between them. Under the assumption that state transitions only depend on the current state of the protein, these can be formulated as Markov models. The gating dynamics can then be described by a system of ordinary differential equations. This formalism can not only be used to model receptors but the behavior of gated ion channels generally (Colquhoun and Hawkes 1981) and includes the well-known Hodgkin

Ionotropic Receptors Dynamics, Conductance Models, Fig. 1 Examples of simulated receptor responses. (a), The alpha function Eq. 1 with three different time constants. (b), Comparison of the two state Eq. 2 and three state Eq. 4 models of fast AMPA/Kainate receptor, as derived by Destexhe et al. (1994). Brief

neurotransmitter transients with frequency 100 Hz were modeled as alpha functions with $\tau = 0.1$ ms. Each successive response, as indicated by the fraction of open channels, is identical in the two state model. A slow transition into the desensitized state causes the response to decrease in the three state model

Huxley model as a special case (Hodgkin and Huxley 1952).

The simplest, first-order model of a receptor includes one closed (C) and one open (O) state:

The transition into the open state is proportional to the neurotransmitter concentration $T(t)$ and a binding rate constant k_b . From the open bound state, the receptor relaxes back into the closed state with the rate constant k_u .

For a system of many identical channels, this model can be written as an ordinary differential equation (ODE) describing the fraction of open channels at time t :

$$\frac{dO(t)}{dt} = \underbrace{k_b T(t)(1 - O(t))}_{\text{binding}} - \underbrace{k_u O(t)}_{\text{unbinding}} \quad (3)$$

Since there are two possible states in this model, the relation $O(t) + C(t) = 1$ has to be fulfilled. When the receptor conductance is independent of other factors such as the membrane voltage, the conductance of the channel population is then given by $g = g_{\max} O(t)$, where $g_{\max}$ is the peak conductance. This model produces kinetics similar to alpha functions but can be adjusted to reflect different rise and decay kinetics (Fig. 1b).

A counterexample is the NMDA receptor, where gating also depends on the membrane voltage and the extracellular Mg^{2+} concentration. This can be modeled with a more complex kinetic model, which in a physiological parameter range simplifies to a factor of $g_{\text{NMDA}}(V) = 1/(1 + \exp(-\gamma V)\eta M)$, where M is the Mg^{2+} concentration (Jahr and Stevens 1990).

Kinetic models can be easily extended to include more states, such as a desensitized state D :

As above, this kinetic scheme can be written as a system of ODEs:

$$\begin{aligned} \frac{dO(t)}{dt} &= k_b T(t)C(t) + k_r D(t) - (k_u + k_d)O(t) \\ 1 &= O(t) + C(t) + D(t) \end{aligned} \quad (5)$$

This model shows how receptor desensitization affects the conductance response time course during transmission of a single synaptic event (Fig. 1b; Trussell et al. 1988). Moreover, desensitization also can lead to suppression of the conductance during fast, repetitive activation of a synapse, suggesting an important physiological role for desensitization (Jones and Westbrook 1996; Wong et al. 2003).

It is important to note that in order to precisely reproduce the kinetics of ionotropic receptors, typically more complex models are required. These may, for instance, also include different conductance states that have been identified in single-channel recordings from AMPA receptors (Robert and Howe 2003; Postlethwaite et al. 2007). In general however, three- or four-state models have been shown to be very effective in describing the main features of the responses of AMPA, NMDA, and GABA_A receptors (Destexhe et al. 1994).

Summary

Kinetic models provide good descriptions of the time course of a range of ionotropic receptor responses and also allow for investigating the underlying dynamics of the receptor protein. This formulation can be directly cast into a set of master equations that describe the probability of the occupancy of the different receptor states (Gillespie 1977). Results from stochastic simulations can then be directly compared to experimental measurements of statistical quantities such as dwell times. A drawback of kinetic models is that they can be computationally costly, which is impractical particularly in larger network simulations. Therefore, often simple exponential or alpha function models are used in such cases.

Brain Sciences, Leipzig, Germany

Synonyms

[Jansen model](#); [Jansen-Zetterberg model](#)

Definition

The Jansen-Rit model is a neural population model of a local cortical circuit. It contains three interconnected neural populations: one for the pyramidal projection neurons and two for excitatory and inhibitory interneurons forming feedback loops. Each neural population is described by a second-order differential operator transforming the mean incoming spike rate to the mean membrane potential and a nonlinear function transforming the mean membrane potential to a mean output spike rate.

Detailed Description

The Jansen-Rit model is a neural population model comprising three interconnected neural populations (see Fig. 1). It has been first described by Jansen and colleagues (Jansen et al. 1993; Jansen and Rit 1995) and goes back to earlier work by Lopes da Silva et al. (1974, 1976).

Mathematical Description

The state variables of the model comprise the mean membrane potentials $V(t)$ and the mean firing rates $m(t)$ of the populations. For each population, a rate-to-potential operator (RPO) describes the dynamics of the synapses and dendritic trees, while the potential-to-rate operator (PRO) describes the output nonlinearity at the axonal hillocks. The RPO can be described as an alpha function, which is a Green's function of a second-order differential equation, where τ is a time constant summarizing passive dendritic cable delays and neurotransmitter kinetics in the synapse, H is the synaptic gain, and c is the connection strength:

$$\left(\frac{\partial^2}{\partial t^2} + \frac{2}{T} \frac{\partial}{\partial t} + \frac{1}{T^2} \right) V(t) = \frac{Hc}{T} m(t). \quad (1)$$

This is equivalent to convolving the incoming spike rate with the alpha function, which has been shown to adequately describe the postsynaptic

Jansen-Rit Model, Fig. 1 Schematic drawing of the Jansen-Rit model of a cortical area. Pyramidal cells (PC) send axons to other areas (output). Collaterals contact excitatory and inhibitory interneurons (EIN, IIN), which in turn form feedback loops onto the PC. Excitatory synapses from other brain areas (input) contact all three neural populations. Black triangles symbolize excitatory (marked “+”) or inhibitory (marked “-”) synaptic contacts

potential in response to a single spike, e.g., by Freeman (1975). The PRO is a sigmoid function, where V_0 is the firing threshold, r is the slope reflecting the variance of firing thresholds within the population, and e_0 is the firing rate at threshold:

$$m(t) = \frac{2e_0}{1 + e^{r(V_0 - V(t))}}. \quad (2)$$

This function can be seen as an approximation of the superposition of many Heaviside functions belonging to individual neurons with normally distributed firing thresholds (Liley et al. 2002).

Full Set of Equation

As shown in Fig. 1, the Jansen-Rit model comprises seven synaptic contacts, each of which can be described by Eqs. 1 and 2. In the original parameterization of Jansen et al. (1993), the PRO parameters are kept constant for all populations ($e_0 = 2.5 \text{ s}^{-1}$; $r = 558.7 \text{ V}^{-1}$; $V_0 = 6 \text{ mV}$), and the remaining parameters are only distinguished between excitatory and inhibitory synapses ($\tau_e = 10 \text{ ms}$; $\tau_i = 20 \text{ ms}$; $H_e = 3.25 \text{ mV}$; $H_i = -22 \text{ mV}$). Equations for synapses with the same postsynaptic and the same type of pre-synaptic (excitatory or inhibitory) populations can be combined, which reduces the number of equations to 4. The following definitions normalize the variables and combine some of the parameters in a convenient way (Spiegler 2011):

- Time: $\kappa = t/\tau_c$ with τ_c being a conveniently chosen reference time constant.
- Time constants: $\beta_e = \tau_c/\tau_e$ and $\beta_i = \tau_c/\tau_i$.
- Potential: $x(\kappa) = r \cdot V(\kappa\tau_c)$.
- Firing rate: $z(\kappa) = m(\kappa\tau_c)/(2e_0)$.
- Coupling $a \rightarrow b$: $\alpha_{ba} = 2e_0rc_{ba}H_{e,i}\tau_{e,i}$ with c_{ba} being the connectivity from population a to population b . Population indices a and b can be 1 for EINs, 2 for IINs, 3 for PCs, and T for external input.
- Sigmoid: $\gamma = \exp(rV_0)$.

With these definitions, the differential operator according to Eq. 1 can be reformulated for excitatory and inhibitory synapses as follows:

$$L_{e,i} = \left(\frac{\partial^2}{\partial \kappa^2} + 2\beta_{e,i} \frac{\partial}{\partial \kappa} + \beta_{e,i}^2 \right). \quad (3)$$

The PRO according to Eq. 2 is described by the following sigmoid function:

$$S(x(\kappa)) = \frac{1}{1 + \gamma e^{-x(\kappa)}}. \quad (4)$$

The state variables are now x_{1e} , x_{2e} , x_{3e} (normalized excitatory postsynaptic potentials for all three populations), and x_{3i} (normalized inhibitory postsynaptic potential in the PCs). The normalized external input firing rates are z_{1T} , z_{2T} , z_{3T} . The state equations can now be written as

$$L_e x_{1e}(\kappa) = \beta_e^2 (\alpha_{13} S(x_{3e}(\kappa) + x_{3i}(\kappa)) + \alpha_{1T} z_{1T}(\kappa)), \quad (5)$$

$$L_e x_{2e}(\kappa) = \beta_e^2 (\alpha_{23} S(x_{3e}(\kappa) + x_{3i}(\kappa)) + \alpha_{2T} z_{2T}(\kappa)), \quad (6)$$

$$L_e x_{3e}(\kappa) = \beta_e^2 (\alpha_{31} S(x_{1e}(\kappa)) + \alpha_{3T} z_{3T}(\kappa)), \quad (7)$$

$$L_i x_{3i}(\kappa) = \beta_i^2 (\alpha_{32} S(x_{2e}(\kappa))). \quad (8)$$

Dynamic Properties

In spite of its apparent simplicity, the Jansen-Rit model is capable of producing a surprisingly rich repertoire of dynamic behaviors, which populate

the parameter space in a very complex way. When the neural populations are exposed to constant external input, thus keeping the system in its equilibrium state, the model can produce constant output, harmonic oscillations, and large-amplitude nonharmonic oscillations. The transitions between these phases are characterized by subcritical and supercritical Andronov-Hopf bifurcations, Shil'nikov's homoclinic bifurcations, and further global bifurcations. Bistability occurs in large parts of the parameter space. While Grimbert and Faugeras (2006) investigated the dynamics of the original parameter configuration proposed by Jansen and Rit, Spiegler et al. (2010) systematically investigated the large parts of the parameter space of the model. When the input to the neural populations is oscillatory, the system also produces complex nonharmonic oscillations as well as quasiperiodic and chaotic behavior, depending in a complex fashion on the amplitude and frequency of the input (Spiegler et al. 2011).

Applications

The Jansen-Rit model has been demonstrated to explain a broad range of phenomena in electric brain activity, including epilepsy-like activity (Wendling et al. 2000; Touboul et al. 2011), narrowband brain oscillations (David and Friston 2003), event-related activity (David et al. 2006), and steady-state responses (Moran et al. 2009). Within the framework of dynamic causal modeling (David et al. 2006), networks of Jansen-Rit models were used to account for the outcomes of neuroscientific experiments (e.g., Garrido et al. 2009).

Advantages and Limitations

The Jansen-Rit model is a very parsimonious model of cortical mean-field activity, which retains a considerable degree of biological realism, as it accounts for the major functional roles of neurons: PCs project to distant areas and, due to their asymmetric appearance and aligned arrangement, form the major source of extracranially detectable electric brain signals; interneurons form local positive and negative feedback loops.

The description of the populations by RPO and PRO is also in principal agreement with cell physiological observations. On the other hand, the circuit represents a significant simplification: in reality, many more distinguishable populations are interconnected in a complex fashion. Therefore, it is difficult to map the parameters of the model directly onto the physical properties of neural populations.

Joint Peri Stimulus Time Histogram (JPSTH)

George L. Gerstein¹ and Ad Aertsen²

¹Department of Neuroscience, University of Pennsylvania, Philadelphia, PA, USA

²Bernstein Center Freiburg, Faculty of Biology, University Freiburg, Freiburg, Germany

Definition

The joint peristimulus time histogram (JPSTH) provides the two-dimensional time-resolved

correlation of two neurons with respect to a trigger event. A specific correction removes the effect of the trigger on the individual neuronal responses and thus highlights the excess correlation between the two neurons.

Detailed Description

The temporal relation between two spike trains is usually studied using the ordinary cross-correlation (see entry ► [“Correlation Analysis of Parallel Spike Trains”](#)) together with the shift or peristimulus time histogram (PSTH)-based (see entry ► [“Estimation of Neuronal Firing Rate”](#)) predictor to partially compensate for firing covariation. These measures are averages over the entire length of data and hence ignore dynamics. This means we can only infer the static average interaction between the neurons. A portion of the dynamics may be associated with the repeated presentation of stimulus, and it is this portion that is delineated by the JPSTH (as an average over the presentations). The JPSTH also gives a better approach to extracting excess correlation than do the traditional shift or PSTH predictors (Aertsen et al. 1989; Palm et al. 1988).

Construction of the JPSTH begins with creation of the scatter diagram shown in Fig. 1. For each presentation of the stimulus, we take the stimulus time as origin and lay off the activity of the two neurons, each along its own axis as indicated. Points are then plotted on the plane at all logical ANDs of the several action potentials on each axis. The process is repeated for subsequent stimuli, building up a scatter of points on the plane. Various features of the neural activity will produce regions of higher point density. If, for example, one neuron responds to the stimulus with a brief increase in firing rate, there will be a bar of high density of points parallel to the appropriate axis at a location corresponding to the response latency. If there is a high probability of near coincidences in the two trains of action potentials, there will be a bar of high density of points parallel to the principal diagonal and at a distance from it that represents the latency of the favored near coincidences. There may be

Deceased – George L. Gerstein passed away on March 28, 2018. Upon his decease, Ad Aertsen agreed to become a Co-Author, taking care of updating this Chapter.

G. L. Gerstein: deceased.

modulations of density along this bar, indicating the averaged stimulus-locked modulations of the probability for the near coincidences.

The scatter diagram described in the previous paragraph is constructed at the maximum temporal resolution available in the data, that is, corresponding to a single clock tick. In order to allow statistical manipulation of the point densities, we need to make coarser bins. The appropriate types of bins are shown in Fig. 2. For the JPSTH matrix, we use square bins at the same values that are used for the ordinary PST histograms of each spike train (Fig. 2a). For the region near the principal diagonal, we use the bins indicated in Fig. 2b, producing the PST coincidence histogram. This measures the averaged stimulus-locked near coincidence probability in the same sense as the ordinary PST histogram measures the

averaged stimulus-locked firing probability of each neuron individually (see entry ► [“Estimation of Neuronal Firing Rate”](#)). Finally, by summing along the para-diagonal bins shown in Fig. 2c, we produce the ordinary cross-correlogram of the two spike trains (see entry ► [“Correlation Analysis of Parallel Spike Trains”](#)). Note that since these bins are not of equal length (and hence area), we must either normalize by the bin length or compute a larger matrix so as to allow making all bins of equal length.

We now apply the JPSTH measurement to a set of spike trains produced by a simulator. The simulated circuit arrangement is shown in Fig. 3. The observed neurons “10” and “12” are each “spontaneously” active because of independent and stationary inputs from networks G10 and G12. In addition, a periodic stimulus input briefly elevates firing probabilities for the observed neurons. Finally, there is an excitatory synaptic connection from neuron “10” to neuron “12” whose strength is itself modulated by the stimulus; this is indicated in Fig. 3 by the small square box in the path. The temporal profile of this modulation is an initial rapid rise followed by a slower decay.

The basic JPSTH analysis of these “raw” data is shown in the left half of Fig. 4. At left and below the JPSTH matrix are the ordinary PST histograms of the two units. The abscissa PSTH (for unit 10) is repeated below the histogram grouping at the right of the matrix. Rising towards the upper right is the PST coincidence histogram and at the extreme right is the ordinary cross-correlogram. The PST histograms show the time course of the stimulus-driven increase in firing. As expected from the descriptions of the scatter diagram

Joint Peri Stimulus Time Histogram (JPSTH), Fig. 1 Construction of JPSTH

Joint Peri Stimulus Time Histogram (JPSTH), Fig. 2 Bin arrangements for (a) JPSTH matrix, (b) peristimulus coincidence histogram, (c) cross-correlogram

construction and the simulated circuit used to generate the data, the JPSTH matrix shows a hill, a fairly broad stripe parallel to each axis, and a narrow stripe parallel (just above) the principal diagonal. The PST coincidence histogram shows a broad peak at the times when both neurons have stimulus-induced higher firing rates, which is otherwise fairly small. Finally the cross-correlogram shows a narrow peak near the origin riding on a flat background.

Because the observed neurons are being co-modulated by the direct stimulus input, their firing rates increase and decrease in unison, thus creating a large part of the “raw” correlation structure. In order to infer “effective connectivity” or

Joint Peri Stimulus Time Histogram (JPSTH), Fig. 3 Circuit used to generate spike trains with simulator program

organization among our observed neurons, we need to compare the “raw” correlation to that expected for two independent neurons with precisely the observed PST histograms. This is accomplished with the corrected JPSTH as shown in the right half of Fig. 4. Here we subtract the matrix produced by the bin-by-bin product of the two PST histograms (divided by the number of stimuli) from the “raw” JPSTH matrix and then divide, again bin by bin, by the product of the standard deviations in each PST histogram. Each bin in the matrix has now become a correlation coefficient. PST histograms are shown as before, but the derived coincidence histogram and the cross-correlation are now corrected for firing rate changes (see entries ► “Significance Evaluation” and ► “Surrogate Data for Evaluation of Spike Correlation”). Note that the hill and bars parallel to the axes have disappeared from the corrected JPSTH matrix, while the diagonal stripe has persisted. The corrected PST coincidence histogram shows an initial rapid rise and subsequent slow fall, as expected from the stimulus modulation of the synaptic connection in the simulator. The corrected cross-correlogram shows only a central peak, with no “background” correlation. We note that this matrix-based correction of the cross-correlogram is somewhat different but more accurate than correction based on the more usual shift or PSTH-based predictor. Thus, this correction has extracted the (known) stimulus time-

Joint Peri Stimulus Time Histogram (JPSTH), Fig. 4 (Left) Matrix containing the raw spike coincidences (JPSTH) and the PST coincidence histogram (red) to the

right. The cross-correlogram is shown in orange. (Right) Same display as shown on the left but here for the normalized JPST

locked modulation of the “effective correlation” between the two neurons and has removed the direct correlation effects of the stimulus-related co-modulation of firing rates.

It is necessary to establish significance for the features shown in the corrected JPSTH and its associated histograms and also to deal with non-stationarity in the neural activity. Methods for both objectives have been worked out and are discussed in Palm et al. (1988) and Gerstein (1998). In addition it is not necessary to use square time bins in the JPSTH matrix. For example, the bin resolution perpendicular to the main diagonal can be much higher than along it. This produces a stimulus-locked and time-resolved cross-correlation along the main diagonal (see Gerstein 1998; Aertsen 2021) for more detail). Please find an example application of the JPSTH in Vaadia et al. (1995).

Definition

PET/SPECT is an *in vivo* imaging technique used to quantitate the biodistribution of specific molecules labeled with radioisotopes termed radiotracers, radiopharmaceuticals, or radioligands. A kinetic model is a mathematical expression of the kinetics of radiotracers between compartments, usually defined as the virtual chamber of organs/tissues or as states of the radiotracer. The influx or efflux rate of the radiotracer concentration between compartments is expressed as the product of the

concentration of the radiotracer and the transfer constant and is known as the rate constant. Applying the numerical time course of the radiotracer concentration, arranged by the kinetic model to measure the dynamic PET/SPECT images, the rate constant between compartments, or the combined rate constants can be mathematically estimated as a physiological function. These physiological parameters can be used to diagnose disease and to elucidate the physiology of the brain function.

Detailed Description

What Is a Kinetic Model?

In general, a kinetic model is a mathematical expression regarding the balance of molecules between compartments, which are defined as a virtual chamber for molecules. As shown in Fig. 1, we have assumed a very simple case; the membrane between two compartments A and B and the concentration of the specific molecules, C_A and C_B . If the radioactive molecules are assigned to compartment A at $t = 0$, C_B would

be zero at $t = 0$ and then gradually increase with passive diffusion or facilitated transportation; finally, C_A and C_B would reach an equilibrium condition at $t = t^*$. The influx of molecules into compartment B is given by the product of the concentration of molecules in A and the forward transfer constant k_1 ; the efflux of molecules from compartments B is given by the product of the concentration of molecules in B and the backward transfer constant k_2 , where these constants k_1 and k_2 are called the rate constant (expressed as units of 1/min). The time differentiation of C_B is expressed as the balance between the influx and the efflux as follows:

$$\frac{dC_B(t)}{dt} = k_1 C_A(t) - k_2 C_B(t)$$

This equation can be solved by means of the Laplace transform:

$$C_B(t) = k_1 C_A(t) \otimes \exp(-k_2 t),$$

where $\otimes$ represents the convolution integral. For PET/SPECT, a balance in the concentration of radiotracers between compartments is often assumed in this mathematical model. The compartment A in Fig. 1 is usually regarded as the arterial plasma, which is the supply source of the radiotracer that is taken up into the target organ or tissue. k_1 is often capitalized as K_1 to differentiate it from other rate constants. The unit used for K_1 is $\text{mL} \cdot \text{cm}^{-3} \cdot \text{min}^{-1}$. Because the affinities of the radiotracer for compartment A and compartment B are different, K_1 and k_2 are not identical. The ratio of K_1 to k_2 is called a partition coefficient, which suggests a relative distribution volume of the molecule in compartment B as compared with that in compartment A. This partition coefficient becomes an important parameter for the measurement of blood flow using diffusible radiotracers such as ^{133}Xe or H_2^{15}O , as mentioned later. Furthermore, compartment B is subdivided into two or three compartments, between which there is biological uptake/clearance or some other molecular transportation system involved. Then, the entire compartment model would be much more complicated (Phelps et al. 1979). Table 1 shows

Kinetic Models for PET/SPECT Imaging,
Fig. 1 Example of a simple compartment model

Kinetic Models for PET/SPECT Imaging, Table 1 Typical parameters used in the kinetic model for PET/SPECT imaging

Abbreviation	Description	Units
C_t	Concentration of radioactivity in the (target) tissue	$\text{Bq} \cdot \text{mL}^{-1}$
C_T	Measured concentration of radioactivity using PET/SPECT	$\text{Bq} \cdot \text{cm}^{-3}$
C_W	Concentration of radioactivity in the whole blood	$\text{Bq} \cdot \text{mL}^{-1}$
C_p	Concentration of radioactivity in the plasma	$\text{Bq} \cdot \text{mL}^{-1}$
C_a	Arterial input function	$\text{Bq} \cdot \text{mL}^{-1}$
f	Regional blood flow	$\text{mL} \cdot \text{min}^{-1} \cdot \text{cm}^{-3}$
p	Partition coefficient	$\text{mL} \cdot \text{cm}^{-3}$
P	Permeability	$\text{cm} \cdot \text{min}^{-1}$
S	Surface area per unit tissue volume	$\text{cm}^2 \cdot \text{cm}^{-3}$
V_B	Volume fraction of the arterial blood	Unitless
K_1	Rate constant for transfer from the arterial plasma to the tissue	$\text{mL} \cdot \text{cm}^{-3} \cdot \text{min}^{-1}$
k_2, k_3, k_4	Rate constants	min^{-1}
V_T	Volume of distribution expressed relative to total plasma ligand concentration C_p	$\text{mL} \cdot \text{cm}^{-3}$
BP	<i>In vitro</i> binding potential	
BP_{ND}	<i>In vivo</i> binding potential against nondisplaceable radiotracer	Unitless
B_{avail}	Density of available target molecule for binding radiotracer <i>in vivo</i> , similar concept as B_{max} <i>in vitro</i>	$\text{nmol} \cdot \text{L}^{-1}$
K_D	Dissociation constant of radiotracer to the molecules	$\text{nmol} \cdot \text{L}^{-1}$

typical parameters that are used in the kinetic model for PET/SPECT imaging.

(Meyer et al. 1984). Constant infusion was initially developed using the continuous inhalation of ^{15}O -labeled gaseous radiotracers (Jones et al. 1976).

Radiotracer Administration

Radiotracers for PET/SPECT studies are administered intravenously or by inhalation, pass through the lung and heart, and are delivered to the target organs by the arterial blood. Gaseous radiotracers (e.g., ^{15}O -labeled gas and ^{133}Xe) are administered by inhalation (Lassen et al. 1981; Jones et al. 1976). These inhaled radiotracers are exchanged by transporting across the alveoli in the lungs and are dissolved in the arterial blood in the lung. Nongaseous radiotracer administration is categorized into two types, namely, bolus injection and constant infusion. Bolus injection involves the administration of a single dose of radiotracer over a short period of time via a blood vessel. Constant infusion, taking into consideration the physical decay of the radioisotope and its biological clearance, achieves a steady-state condition ($dC/dt = 0$) in the target organ

Radiotracer in the Blood

A radiotracer, which will eventually be delivered to the target tissue, distributes in the arterial blood in several ways that include it being (i) freely diffusible between the plasma and blood cells, (ii) mostly soluble in the plasma while partially binding to the blood cells, or (iii) mostly soluble in the plasma while partially binding to the plasma proteins and blood cells. For example, H_2^{15}O freely mixes between the plasma and blood cells. The arterial radiotracer concentration in the whole blood, C_W , corresponds to the arterial input function, C_a (Herscovitch et al. 1983). In the case of a neuroreceptor PET/SPECT study, the administered radiotracer in the plasma is transferred across the blood–brain barrier (BBB) into the brain tissue (Seibyl et al. 1992), and the plasma

radioactivity concentration, C_p , corresponds to the arterial input function, C_a .

Radiotracer in the Tissue

After delivery to the target organ, a radiotracer's uptake or clearance behavior is dependent on its pharmacological or physiological properties. There are several types of uptake mechanisms, such as passive diffusion through the BBB, binding to specific molecules, and metabolic trapping. For example, diffusible radiotracers such as $H_2^{15}O$ exhibit passive diffusion from the artery to the tissue (Raichle et al. 1983). Radiotracers used to target neuroreceptors or for pathological imaging are designed to bind to specific target proteins (e.g., receptor, transporter, and plaque) (Wagner Jr 1986; Bacskai et al. 2002). The most popular radiotracer, ^{18}F -FDG, is metabolically trapped in the tissue by means of a metabolizing enzyme reaction (Reivich et al. 1979), while $[^{11}C]$ raclopride is the most common radiotracer to image dopamine D2/D3 receptors in the brain.

There are several types of clearance such as passive diffusion, unbinding, metabolic (enzyme reactions), and excretion. Furthermore, the property of the radiotracer that is dominant in the target organ during PET/SPECT scans, namely, uptake or clearance, really depends on the design of the compartment model; this includes whether or not the type of kinetics is reversible or irreversible (to the former compartment).

Compartment Models for PET/SPECT

On the assumption that the model can also be simplified in terms of physiological or pharmacological processes, several mathematical compartment models have been proposed and used clinically (Watabe et al. 2006; Schmidt and Turkheimer 2002; Heiss and Herholz 2006).

1-Tissue 2 Compartment Model (1T2CM)

This model, which is shown in Fig. 2a, is the simplest model and involves two parameters; K_1 [$mL \cdot cm^{-3} \cdot min^{-1}$] is a rate constant for the transfer of

Kinetic Models for PET/SPECT Imaging, Fig. 2 Examples of reversible and irreversible compartment models for the human body. (a) 1T2CM, (b) 2T3CM, and (c) 3T4CM

radiotracer from the arterial plasma to the tissue, and k_2 [min^{-1}] is a rate constant for the transfer of radiotracer in the reverse direction. It should be noted that if the model can be regarded as an irreversible type, k_2 can be negligible in the microsphere model (1T2CM) (Kuhl et al. 1982). C_a [$\text{Bq} \cdot \text{ml}^{-1}$] is the so-called arterial input function, and C_t [$\text{Bq} \cdot \text{cm}^{-3}$] is the radioactivity concentration in an organ/tissue. The time differentiation of C_t is expressed as the balance between influx and efflux, and this equation can be solved as mentioned above.

$$\begin{aligned}\frac{dC_t(t)}{dt} &= K_1 C_a(t) - k_2 C_t(t) \\ C_t(t) &= K_1 C_a(t) \otimes \exp(-k_2 t)\end{aligned}$$

The physiological definition of K_1 is often regarded as being “regional blood flow”; however, first-pass extraction, E , of the tracer into the target tissue affects the relationship between the regional blood flow f and K_1 (Ishizu et al. 1996). K_1 is calculated as follows:

$$K_1 = f \cdot E = f \cdot \left(1 - e^{-\frac{PS}{f}}\right),$$

where P is the permeability of the radiotracer across the capillary membrane and S is the capillary surface area per unit volume of the tissue. The equation for the extraction is known as the Renkin-Crone model, in which it is assumed that the capillary is a rigid cylindrical tube (Renkin 1959; Crone 1963). If the product of P and S is large, such as in the case of H_2^{15}O , E becomes almost unity and K_1 can be regarded as f . Furthermore, if the radiotracer only distributes through passive diffusion, the efflux (clearance from the tissue to the blood) would be proportional to the influx divided by the tissue/blood partition coefficient of the radiotracer p :

$$\frac{dC_t(t)}{dt} = K_1 C_a(t) - \frac{K_1}{p} C_t(t)$$

Then, the 1T2CM can be arranged according to the following equation:

$$C_t(t) = K_1 C_a(t) \otimes \exp\left(-\frac{K_1}{p} t\right)$$

If p can be assumed a constant, the above equation has only one parameter of K_1 to be solved.

2-Tissue 3 Compartment Model (2T3CM)

This model has four parameters, namely, K_1 [$\text{mL} \cdot \text{cm}^{-3} \cdot \text{min}^{-1}$], k_2 , k_3 , and k_4 [min^{-1}]. If k_4 is negligible in the 2T3CM, the model can be one of the irreversible types as shown in Fig. 2b. Two compartments in the tissue express two different statuses of the radiotracer concentration of the nondisplaceable (C_{nd} [$\text{Bq} \cdot \text{cm}^{-3}$]) and specific compartments (C_s [$\text{Bq} \cdot \text{cm}^{-3}$]). The $C_s(t)$ compartment represents radiotracer that is specifically bound to the target molecules and is usually the compartment of interest to be observed. The $C_{nd}(t)$ compartment includes free and non-specifically bound radiotracer. Exchanges of radiotracer concentration between compartments are governed by simple linear differential equations:

$$\begin{aligned}\frac{dC_{us}(t)}{dt} &= K_1 C_a(t) - (k_2 + k_3) C_{nd}(t) + k_4 C_s(t) \\ \frac{dC_s(t)}{dt} &= k_3 C_{nd}(t) - k_4 C_s(t)\end{aligned}$$

Total radioactivity concentration C_t [$\text{Bq} \cdot \text{cm}^{-3}$] is expressed as the summation of two compartments as follows:

$$\begin{aligned}C_t(t) &= C_{nd}(t) + C_s(t) \\ C_t(t) &= \frac{K_1}{\alpha_1 - \alpha_2} \{(\alpha_1 - k_3 - k_4)e^{-\alpha_1 t} - (\alpha_2 - k_3 - k_4)e^{-\alpha_2 t}\} \otimes C_a(t). \\ \alpha_{1,2} &= \frac{k_2 + k_3 + k_4 \pm \sqrt{(k_2 + k_3 + k_4)^2 - 4k_2k_4}}{2}\end{aligned}$$

3-Tissue 4 Compartment Model (3T4CM)

This is a more complicated model involving six parameters, namely, K_1 [$\text{mL} \cdot \text{cm}^{-3} \cdot \text{min}^{-1}$], k_2 , k_3 , k_4 , k_5 , and k_6 [min^{-1}]. The combination of these six parameters is very flexible in designing the model, and an example of a 3T4CM is shown in Fig. 2c. In this figure, the nonspecific compartment C_{ns} in the tissue is divided into two statuses, free and nonspecific binding (C_f and C_{nsb} , respectively). Differential equations for each of the concentrations $C_s(t)$, $C_f(t)$, and $C_{nsb}(t)$ are shown below.

$$\begin{aligned}
\frac{dC_s(t)}{dt} &= k_3 C_f(t) - k_4 C_s(t) \\
\frac{dC_f(t)}{dt} &= K_1 C_a(t) + k_6 C_{nsb}(t) + k_4 C_s(t) \\
&\quad - (k_2 + k_3 + k_4) C_f(t) \\
\frac{dC_{usb}(t)}{dt} &= k_5 C_f(t) - k_5 C_{nsb}(t) \\
C_t(t) &= C_f(t) + C_s(t) + C_{nsb}(t)
\end{aligned}$$

There is an analytical solution for the 3T4CM, but its estimates become practically unstable with noisy data. Instead, some simplification, in other words a reduction in the number of compartments by combining relatively similar compartments to each other (e.g., C_f and C_{nsb}), will help in solving the model parameters (refer to the simplified reference tissue model for PET receptor studies (SRTM) developed by Lammertsma and Hume (1996)).

Estimation of Model Parameters

Blood Volume Component

The use of a kinetic model together with the time course of change in the radioactivity concentration $C_t(t)$ allows us to estimate detailed physiological parameters. To measure $C_t(t)$ in the target, PET/SPECT dynamic data sets, which are a series of discrete time-related data points, are acquired for 1–2 h or more in cases where the tracer has a longer biological or physical half-life. Strictly speaking, the measured radioactivity concentration in the corresponding region of the tissue $C_T(t)$ [Bq · cm⁻³] is not equal to the previously defined radio-tracer concentration, $C_t(t)$ [Bq · mL⁻¹], and there is a relationship between $C_T(t)$ and $C_t(t)$:

$$C_T(t) = (1 - V_B)C_t(t) + \rho \cdot V_B C_W(t),$$

where V_B is the fraction of the measured volume occupied by the blood, ρ [mL · cm⁻³] is the density of the tissue, and $C_W(t)$ is the radioactive concentration in the whole arterial blood. Because the brain tissue usually has a small fraction of its volume occupied by the blood (about 5%) (Leenders et al. 1990), the influence of the blood volume parameter is not so large. However, if V_B is large, such as in the renal tissue where it is about

15 % (Kudomi et al. 2009), $C_T(t)$ must be considered to include the V_B parameter.

Nonlinear Least Square Fitting

For estimation of parameters in the model from the measured PET/SPECT dynamic data, the nonlinear least square (NLLS) fitting technique (implemented with a modified Marquardt algorithm (More 1978) or simplex algorithm (Nelder and Mead 1965)) is often used while searching the minimum summed residuals S between measured and modeled time-activity curves (TACs). S is calculated as follows:

$$\begin{aligned}
S &= \sum_t w(t) \{C_T(t) - [(1 - V_B)C_t(t) + \rho V_B C_a(t)]\}^2 \\
(K_1, k_2, \dots, V_B) &= \arg \min (S),
\end{aligned}$$

where $w(t)$ is the weighting factor for the residuals and is often set to 1. However, in the case of a steep TAC or a short half-life radioisotope such as ¹¹C ($T_{1/2} = 20$ min), it is sometimes necessary to adjust the $w(t)$ values such as (frame duration)²/(total counts) (Gunn et al. 1998).

In fitting parameters using the NLLS technique, there are sometimes circumstances in which many solutions for the estimated parameters exist. To avoid convergence to a local minimum (i.e., not the correct estimations), the initial values for the estimated parameters are very important. The estimates obtained from NLLS fitting fluctuate unstably because of statistical noise regarding the measured $C_T(t)$. Therefore, an initial value at a specific $C_T(t)$ is often set to the first $C_T(t)$ estimate for the averaged surrounding regions with less noise than the specific $C_T(t)$. The disadvantage of NLLS fitting is the long computing time required. This disadvantage is significant in the case of voxel-by-voxel estimation, but not in the case of region-of-interest estimation.

Selection of the Compartment Model

In some cases, it is not clear if the 1T2CM or 2T3CM is better adapted to the measured $C_T(t)$. To select which model would be better, statistical tests such as the F test, Akaike's information criterion (AIC), or Schwarz criterion are

performed. AIC (Akaike 1987) is defined as follows:

$$\text{AIC} = n \ln S + 2m,$$

where n is the number of time frames, S is the residual of the fitting procedure, and m is the number of estimates. The preferred model gives the minimum AIC value.

Distribution Volume

In solving the compartment model, the smallest element to be determined is the k parameter. However, if the number of k parameters is increased, the estimated parameters become unstable and variable; in addition, a lengthy calculation time is required for large iterative processes. Therefore, compartment modeling in PET/SPECT often uses combined parameters rather than the individual k parameters themselves.

The distribution volume is one of the most frequently used combined parameters. The basic concept behind it originated from the volume of distribution of the pharmacokinetics, that is, an apparent plasma volume which is equivalent to the administered dose to be evaluated. This concept is widely adopted in the field of *in vivo* radio-tracer imaging. Instead of referring to the total administrated dose in the entire body, the distribution volume (V_T) is expressed as the activity of radiotracer in the tissue as follows:

$$V_T = \frac{C_T}{C_a} = \sum_i V_i = \sum_i \frac{C_{Ti}}{C_a},$$

where C_{Ti} and V_i are the radioactivity concentrations and the distribution volume under specific condition i in the tissue. An important assumption here is that the radioactive concentration in V_T must satisfy the equilibrium condition. However, it is practically difficult to achieve complete equilibrium because of the total loss from an open system, where radiotracer gradually flows out. In the case of exchange between compartments in neuroreceptor studies, the term “transient equilibrium,” where the maximum turning point in radioactivity concentration occurs, is used (Ito et al. 1998; Farde et al. 1989).

Binding Potential

The binding potential (BP) is one of the most frequently used combined parameters. BP represents the ability of a radiotracer to bind to specific target molecules. Binding ability depends on both the density of the available target molecule (B_{avail}) and the affinity of the radiotracer for the molecule ($1/K_D$) (Innis et al. 2007). Instead of estimating and handling B_{avail} and $1/K_D$ individually, it is convenient to use a combined parameter such as BP . For the reversible 2T3CM, BP usually represents BP_{ND} , which is the binding potential regarding a nondisplaceable radiotracer (Innis et al. 2007) and can also be expressed by the ratio of distribution volumes as follows:

$$BP_{\text{ND}} = \frac{V_s}{V_{\text{nd}}} = \frac{(V_1 - V_{\text{nd}})}{V_{\text{nd}}} = \frac{V_T}{V_{\text{nd}}} - 1$$

If the BP_{ND} is high, the radiotracer can be regarded as having a good signal-to-noise property for quantitating/visualizing the target-to-background tissue contrast. The distribution volume of each compartment can be calculated by combining the rate constants. For example, in the reversible 2T3CM, assuming that both C_{nd} and C_s simultaneously reach an equilibrium, differentiations of dC_{nd}/dt and dC_s/dt become zero as follows:

$$\begin{aligned} \frac{dC_{\text{nd}}(t)}{dt} &= K_1 C_a(t) - (k_2 + k_3) C_{\text{nd}}(t) + k_4 C_s(t) \\ &= 0 \\ \frac{dC_s(t)}{dt} &= k_3 C_{\text{nd}}(t) - k_4 C_s(t) = 0 \end{aligned}$$

After arrangement of these equations, the distribution volumes as an expression of the rate constant are as follows:

$$\begin{aligned} V_{\text{nd}} &= \frac{C_{\text{nd}}}{C_a} = \frac{K_1}{k_2} \\ V_s &= \frac{C_s}{C_a} = \frac{K_1}{k_2} \cdot \frac{k_3}{k_4} \\ V_T &= V_{\text{nd}} + V_s = \frac{K_1}{k_2} \cdot \left(1 + \frac{k_3}{k_4}\right) \end{aligned}$$

Therefore, the BP_{ND} can be rewritten as follows:

$$BP_{ND} = \frac{k_3}{k_4}$$

In clinical situation, BP_{ND} is useful outcome measure, and its determination has been investigated for each radiotracer. For imaging of the most common radiotracer in neuroreceptor, [^{11}C] raclopride, it is well known that BP_{ND} is quantitatively estimated using the SRTM (Lammertsma and Hume 1996). However, in some cases (such as translocator protein (TSPO) imaging), kinetic property of the radiotracer is much more complicated than [^{11}C] raclopride due to low specific/nonspecific binding ratio and no apparent reference tissue region, and it is usually difficult how to optimize the estimation (Ikoma et al. 2007).

Graphical Plot

Instead of the estimation of NLLS as one of the alternative estimation processes, graphical analysis or a “graphical plot” is often used to shorten the computing time. This graphical plot is very useful not only because of the rapid calculation time but also because of the stability of the estimates (Yokoi et al. 1993; Patlak et al. 1983; Logan et al. 1990). For example, the time-differential equation in the 1T2CM is integrated from time zero to time t and then divided by the integration of the arterial input function as follows (van den Hoff et al. 1993).

$$\frac{C_t(t)}{\int_0^t C_a(\tau) d\tau} = K_1 - k_2 \frac{\int_0^t C_t(\tau) d\tau}{\int_0^t C_a(\tau) d\tau}$$

The formula can be regarded as $Y = K_1 - k_2 \cdot X$, where X and Y vary with t . So a plot of Y against X should give a straight line with gradient k_2 and intercept K_1 . Once the observed $C_t(t)$ can be adapted to this linearization, both K_1 and k_2 can be uniquely estimated, with a shorter calculation time than that required for the estimation of the NLLS.

Furthermore, in the irreversible 2T3CM, the Gjedde-Patlak plot can be used as a graphical plot. Its formula is as follows (Patlak et al. 1983).

$$\frac{C_T(t)}{C_a(t)} = \frac{K_1 k_3}{k_2 + k_3} \frac{\int_0^t C_a(u) du}{C_a(t)} + bt \geq t^*,$$

where the gradient, $K_1 k_3 / (k_2 + k_3)$, is used to estimate the cerebral metabolic rate of glucose (CMRglu) in the FDG-PET study. CMRglu is calculated as follows:

$$\text{CMRgluc} = \frac{K_1 k_3}{k_2 + k_3} \cdot \frac{C_p}{LC},$$

where C_p is the arterial plasma glucose concentration and LC is the lumped constant, which is used to convert the $K_1 k_3 / (k_2 + k_3)$ of FDG to the glucose concentration. For the 1T2CM or 2T3CM reversible compartment models, Logan graphical analysis (the so-called Logan plot) is often used, and its formula is as follows:

$$\frac{\int_0^t C_T(u) du}{C_T(t)} = V_T \frac{\int_0^t C_a(u) du}{C_T(t)} + bt \geq t^*,$$

where V_T is the distribution volume. Figure 3 also shows a schematic of the Logan plot. Once $C_t(t)$ and $C_a(t)$ (Fig. 3a, b) are converted (Fig. 3c), the slope of the fitted line from $t^* < t$, V_T can be easily estimated.

Another approach consists of rearranging the Logan plot equation into a multilinear form to give the following formula (Ichise et al. 2002).

$$C_T(t) = \beta_1 \int_0^t C_a(u) du + \beta_2 \int_0^t C_T(u) du \geq t^*,$$

where $\beta_1 = -V_T/b$ and $\beta_2 = 1/b$ are estimated by linear regression analysis of $t \geq t^*$ and V_T is calculated as $-\beta_1/\beta_2$. This approach is usually called multilinear analysis.

Estimation of Arterial Input Function

In general, a kinetic model requires an arterial input function (C_a). To avoid invasiveness, the arterial input function is derived not only from blood sampling but also from image-based estimation. If the heart cavity (left ventricle) is scanned and imaged simultaneously with the

Kinetic Models for PET/SPECT Imaging, Fig. 3 Examples of graphical analysis of the PET/SPECT data sets. (a) arterial input function (C_a); (b) tissue time-

activity curve (C_T) generated using the 2T3CM model with $K_1 = 0.33$, $k_2 = 0.11$, $k_3 = 0.08$, $k_4 = 0.04$, and $V_B = 0$; (c) implementation of the Logan plot with t^*

target organ/tissue, the arterial input function can be directly derived from dynamic images (Watabe et al. 2005; Iida et al. 1998). Alternatively, the input function can be extracted as a component by means of image processing of dynamic images (Zanotti-Fregonara et al. 2012; Wu et al. 1995; Schain et al. 2013; Qiu et al. 2009; Naganawa et al. 2005, 2008; Jiao et al. 2013). However, in cases where there is a requirement for the separation of the plasma radioactivity concentration $C_p(t)$ from that of the whole blood, it is impossible to extract the input function from PET/SPECT images.

Simplification of the Model

In some applications for receptor studies, the arterial input function can be replaced by a reference tissue devoid of specific binding sites. A typical derivation of such a noninvasive technique is the SRTM (Lammertsma and Hume 1996), reference Logan plot (Logan et al. 1996), and multilinear reference tissue model (MRTM) (Ichise et al. 2003).

The SRTM yields the binding potential value by replacing the arterial input function arithmetically from model equations by TAC for the reference region, where specific bindings are negligible; it is assumed that the distribution volume of the nondisplaceable compartment is equal in the target and reference regions and that a target

region can be described using the reversible one-tissue compartment model.

$$C_T(t) = R_1 \cdot C_R(t) + \left(k_2 - \frac{R_1 k_2}{1 + BP_{ND}} \right) \cdot e \left(- \frac{k_2}{1 + BP_{ND}} t \right) \otimes C_R(t),$$

$$R_1 = K_1 / K_1^r$$

where C_T and C_R are the radioactivity concentrations in the target and reference regions, respectively. The SRTM estimates three parameters, namely, the delivery ratio of the target region to the reference region (R_1), the clearance rate constant for the target region (k_2), and the binding potential referred to as BP_{ND} using the NLLS technique. In the case of a voxel-by-voxel estimation, the basis function method that prepares a considerable number of TACs in advance is often used (Gunn et al. 1997).

The reference Logan plot is a linear regression method that is used for the estimation of the binding potential while using the TAC from a reference region instead of the arterial input function.

$$\frac{\int_0^t C_T(u) du}{C_T(t)} = \text{DVR} \cdot \frac{\int_0^t C_R(u) du}{C_T(t)} + bt \geq t^*,$$

$$\text{DVR} = \frac{V_T}{V_{Tr}} = 1 + BP_{ND}$$

where DVR is the ratio of the distribution volumes in the target (V_T) and the reference region (V_{Tr}).

Because V_{Tr} can be regarded as V_{nd} (described in section "Binding Potential") (DVR-1) would be the estimates of the binding potential.

The MRTM also yields the binding potential value using a TAC from the reference region as follows:

$$C_T(t) = \gamma_1 \int_0^t C_R(u) du + \gamma_2 \int_0^t C_T(u) du - \gamma_3 t \geq t^*$$

$$\gamma_1 = -\frac{V_T}{V_{Tr}b}$$

$$\gamma_2 = \frac{1}{b}$$

$$\gamma_3 = -\frac{V_T}{V_{Tr}k_{2r}b},$$

where k_{2r} is the clearance rate constant for the reference region n and γ_1 , γ_2 , and γ_3 are estimated using linear regression analysis for $t \geq t^*$. BP_{ND} can be calculated from the ratio of the two regression coefficients as $BP_{ND} = -(\gamma_1/\gamma_2 + 1)$. Furthermore, if k_{2r} is fixed in the MRTM (termed the MRTM2), the number of the estimates can be reduced from three to two, and a more robust estimation of BP_{ND} can be obtained.

Although these approaches have several advantages such as noninvasiveness over the method requiring an arterial input function, several assumptions are associated with the simplified technique, and caution is mandatory for its use.

Kinetic Models of Postsynaptic Currents

Alain Destexhe

Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

Modeling synaptic currents and conductances is a central aspect of network simulations. The type of model for synaptic currents depends on the receptor type present in the synapse, as well as if one needs to include mechanisms such as the saturation of successive synaptic events and synaptic depression or facilitation. Kinetic models can provide a way to model these interactions in a compact form and can be analytic in some cases, leading to very fast algorithms to simulate synaptic interactions.

Detailed Description

Introduction

Synaptic currents and conductances represent the most common type of interaction between neurons, and they must be simulated in neuronal networks using the most efficient model as possible. It was shown previously that simplified

two-state kinetic models can be used to simulate postsynaptic currents with a reasonable degree of accuracy (Destexhe et al. 1994a, 1998), as an alternative to the more complex Markov models. This approach is similar in spirit to the classic Hodgkin and Huxley (1952) model of action potentials, in which the voltage-dependent currents are also described by two-state kinetic models (reviewed in Destexhe et al. 1994b). We overview here these kinetic models and their fitting to experimental recordings.

Two-State Kinetic Models

The essential properties of ion channel activation can be captured by simplified kinetic models with just two states. The simplest kinetic models for the gating of different classes of ion channels are illustrated in Table 1. For synaptic currents (Destexhe et al. 1994a, 1998), as for voltage-dependent currents (Destexhe et al. 1994b), simplified kinetic models provide an efficient way to incorporate their basic properties, such as the time course of rise and decay and their summation

Kinetic Models of Postsynaptic Currents, Table 1 Two-state kinetic models of different classes of ion channels. *Voltage-dependent channels*: the channel is assumed to have opened (O) and closed (C) states modulated by voltage-dependent transition rates (α and β). *Calcium-dependent channels*: in this case, the opening of the channel depends on the binding of one or several intracellular Ca^{2+} ions (Ca_i). *Transmitter-gated channels*: molecules of neurotransmitter (T) are released transiently and bind to the channel, leading to its opening. *Second messenger-gated channels*: in this case, the opening of the channel is provided by the binding of one or several intracellular second messengers (G). Kinetic equations allow to describe all these processes, which underlie electrophysiological properties and synaptic interactions, using the same formalism (Destexhe et al. 1994b)

Voltage-dependent gating (Hodgkin-Huxley)	$C \xrightleftharpoons[\beta(V)]{\alpha(V)} O$
Calcium-dependent gating	$C + n \text{Ca}_i \xrightleftharpoons[\beta]{\alpha} O$
Transmitter gating	$C + n T \xrightleftharpoons[\beta]{\alpha} O$
Second messenger gating	$C + n G \xrightleftharpoons[\beta]{\alpha} O$

behavior, in simulations that do not require a great level of detail. Typical examples of this kind are simulations of networks of neurons where the most salient features of ion channel interactions must be represented with maximal computational efficiency.

In synaptic currents, however, one must specify the time course of the transmitter concentration (T in Table 1). The simple model for transmitter time course is a square pulse, based on experiments in excised membrane patches which showed that 1 ms pulses of 1 mM glutamate reproduced PSCs that were quite similar to those recorded in the intact synapse (Hestrin 1992; Colquhoun et al. 1992; Standley et al. 1993). The simplest model is to assume that the transmitter, either glutamate or GABA, is released according to a pulse when an action potential invades the presynaptic terminal. Then, a two-state (open/closed) kinetic scheme (as in Table 1), combined with such a pulse of transmitter, can be solved analytically (Destexhe et al. 1994a). The same approach also yields simplified algorithms for three-state and higher schemes (Destexhe et al. 1994b). As a consequence, extremely fast algorithms can be used to simulate most types of synaptic receptors because no differential equation must be solved for synaptic currents (Destexhe et al. 1994a).

AMPA-Kainate Receptors The simplest model that approximates the kinetics of the fast AMPA/kainate type of glutamate receptors can be represented by the two-state diagram:

where α and β are voltage-independent forward and backward rate constants. If r is defined as the fraction of the receptors in the open state, it is then described by the following first-order kinetic equation:

$$\frac{dr}{dt} = \alpha[T] (1 - r) - \beta r, \quad (2)$$

and the postsynaptic current I_{AMPA} is given by:

$$I_{AMPA} = \dot{g}_{AMPA} r(V - E_{AMPA}), \quad (3)$$

where $\bar{g}_{AMPA}$ is the maximal conductance, E_{AMPA} is the reversal potential, and V is the postsynaptic membrane potential.

The best fit of this kinetic scheme to whole-cell recorded AMPA/kainate currents (Fig. 1a) gave $\alpha = 1.1 \times 10^6 M^{-1}s^{-1}$ and $\beta = 190 s^{-1}$ with $E_{AMPA} = 0 mV$ (Destexhe et al. 1998).

NMDA Receptors A unique property of NMDA receptors is that they are voltage dependent and activate only for depolarized membrane potentials. The activation properties NMDA-mediated postsynaptic currents can be represented with a two-state model similar to AMPA/kainate receptors, with a slower time course and a voltage-dependent term. The voltage dependence of NMDA receptor channels is due to its sensitivity to block by physiological concentrations of Mg^{2+}

(Nowak et al. 1984; Jahr and Stevens 1990a, b). The Mg^{2+} block is voltage dependent, allowing NMDA receptor channels to conduct ions only when depolarized. The necessity of both presynaptic and postsynaptic gating conditions (presynaptic neurotransmitter and postsynaptic depolarization) makes the NMDA receptor a molecular coincidence detector. Furthermore, NMDA currents are carried partly by Ca^{2+} ions, which may also play a role in triggering intracellular biochemical cascades.

Using the same scheme as Eqs. 1 and 2, the postsynaptic current is given by:

$$I_{NMDA} = \dot{g}_{NMDA} B(V) r(V - E_{NMDA}), \quad (4)$$

where $\bar{g}_{NMDA}$ is the maximal conductance, E_{NMDA} is the reversal potential, and $B(V)$ represents the magnesium block of the channel. The magnesium block of the NMDA receptor channel is an

Kinetic Models of Postsynaptic Currents, Fig. 1 Best fits of simplified kinetic models to averaged postsynaptic currents obtained from whole-cell recordings. (a). AMPA/kainate-mediated currents (Obtained from Xiang et al. (1992); recorded at 31 °C). (b). NMDA-mediated currents (Obtained from Hessler et al. (1993); recorded at 22–25 °C in Mg^{2+} -free solution). (c). $GABA_A$ -mediated currents.

(d). $GABA_B$ -mediated currents (c–d recorded at 33–35 °C by Otis et al. 1992, 1993). For all graphs, the averaged recording of the synaptic current (noisy trace) is represented with the best fit obtained using the models (continuous trace). Transmitter time course was a pulse of 1 mM and 1 ms duration in all cases (a–d: Modified from Destexhe et al. (1994b, 1996, 1998))

extremely fast process compared to the other kinetics of the receptor (Jahr and Stevens 1990a, b). The block can therefore be accurately modeled as an instantaneous function of voltage (Jahr and Stevens 1990b):

$$B(V) = \frac{1}{1 + \exp(-0.062 V) [\text{Mg}^{2+}]_o / 3.57}, \quad (5)$$

where $[\text{Mg}^{2+}]_o$ is the external magnesium concentration (1–2 mM in physiological conditions).

The best fit of this kinetic scheme to whole-cell recorded NMDA currents (Fig. 1b) gave $\alpha = 7.2 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ and $\beta = 6.6 \text{ s}^{-1}$ with $E_{\text{NMDA}} = 0 \text{ mV}$ (Destexhe et al. 1998).

GABA_A Receptors GABA_A receptors can also be represented by the scheme in Eqs. 1 and 2, with the postsynaptic current given by:

$$I_{\text{GABA}_A} = \dot{g}_{\text{GABA}_A} r (V - E_{\text{GABA}_A}), \quad (6)$$

where $\dot{g}_{\text{GABA}_A}$ is the maximal conductance and E_{GABA_A} is the reversal potential.

The best fit of this kinetic scheme to whole-cell recorded GABA_A currents (Fig. 1c) gave $\alpha = 5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ and $\beta = 180 \text{ s}^{-1}$ with $E_{\text{GABA}_A} = -80 \text{ mV}$ (Destexhe et al. 1998).

GABA_B Receptors and Neuromodulators In the three types of synaptic receptors discussed above, the receptor and ion channel are both part of the same protein complex, and these receptors are called “ionotropic.” In contrast, other classes of synaptic response are mediated by an ion channel that is not directly coupled to a receptor but rather is activated (or deactivated) by an intracellular “second messenger” that is produced when neurotransmitter binds to a separate receptor molecule. These so-called “metabotropic” synaptic responses generally affect K^+ channels but can also affect other channels or biochemical processes. This is the case for GABA_B receptors, whose response is mediated by K^+ channels that are activated by G-proteins (Dutar and Nicoll 1988).

One of the fundamental properties of GABA_B receptors is that they are strongly dependent on the pattern of presynaptic spikes. There are no GABA_B-mediated responses for single or isolated presynaptic spikes, but GABA_B responses appear with intense presynaptic activity such as typically with bursts of presynaptic spikes (Dutar and Nicoll 1988; Davies et al. 1990; Kim et al. 1997). It was shown that such properties can be due to nonlinear properties in the activation kinetics of these receptors (Destexhe and Sejnowski 1995), a hypothesis which was later confirmed by paired recordings of neurons connected with GABA_B receptors (Kim et al. 1997; Thomson and Destexhe 1999).

These nonlinear activation properties of GABA_B responses, unfortunately, cannot be handled correctly by a two-state model. The simplest model of GABA_B-mediated currents has two variables and was obtained from a more complex model (Destexhe and Sejnowski 1995) and is given by:

$$\begin{aligned} \frac{dr}{dt} &= K_1 [T] (1 - r) - K_2 r \\ \frac{ds}{dt} &= K_3 r - K_4 s, \\ I_{\text{GABA}_B} &= \dot{g}_{\text{GABA}_B} \frac{s^n}{s^n + K_d} (V - E_K) \end{aligned} \quad (7)$$

where r is the fraction of receptor in the activated (transmitter-bound) state, s is the second messenger (G-protein) concentration, $\dot{g}_{\text{GABA}_B} = 1 \text{ nS}$ is the maximal conductance of K^+ channels, $E_K = -95 \text{ mV}$ is the potassium reversal potential, and $K_1 \dots K_4$ are rate constants. Fitting of this model to whole-cell recorded GABA_B currents (Fig. 1d) gave the following values: $K_d = 100 \text{ } \mu\text{M}^4$, $K_1 = 9 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, $K_2 = 1.2 \text{ s}^{-1}$, $K_3 = 180 \text{ s}^{-1}$, and $K_4 = 34 \text{ s}^{-1}$ with $n = 4$ binding sites (Destexhe et al. 1998). This model was found to correctly capture the dynamical properties of GABA_B responses in thalamic slices (see Destexhe et al. 1996).

Many other types of neurotransmitters are involved in metabotropic responses on specific receptor types. This is the case for glutamate (through metabotropic receptors), acetylcholine

(through muscarinic receptors), noradrenaline, serotonin, dopamine, histamine, opioids, and others. These neurotransmitter systems have been shown to mediate slow intracellular responses via the intracellular activation of G-proteins, which may affect ionic currents as well as the metabolism of the cell. As with GABA acting on GABA_B receptors, the main electrophysiological target of many neuromodulators is to open or close K⁺ channels (reviewed in McCormick 1992). The model of GABA_B responses outlined above could thus be used to model these currents, with rate constants adjusted to fit the time courses reported for the particular responses (see details in Destexhe et al. 1994b).

Discussion

In this chapter, we reviewed simple models for the main types of synaptic receptors found in the nervous system, namely, the glutamate AMPA and NMDA receptors and the GABAergic GABA_A and GABA_B receptors. It is important to keep in mind that the models shown here are among the simplest models that capture the time course and kinetics of these synaptic receptors, while there exist a wide variety of more complex models (see Destexhe et al. 1998 for an overview of simple and complex models). The main target of simple kinetic models is to be included in network simulations, where computational efficiency is an essential concern. With pulses of transmitted, it is possible to solve these models and obtain an analytic expression for the postsynaptic conductance (Destexhe et al. 1994a). These models are therefore very fast to simulate since no differential equation must be added to model synaptic interactions.

Definition

The olfactory bulb (OB) is a small, self-contained system that is pivotally involved in generating the

sense of the smell. Large-scale models of the olfactory bulb reconstruct extensive portions of it, including the main neuron populations (i.e., mitral, tufted, and granule cells), along with their connectivity and glomerular organization. Large-scale models of the OB therefore comprise of three components: (i) a model of odor inputs, (ii) cell models of the main neuron classes, and (iii) computational models of feedforward and/or feedback inhibition.

Detailed Description

Analyses of large portions of the olfactory bulb (OB) are the key to understand odor processing. In the OB, odor-specific spatiotemporal patterns characterize odor response (Abraham et al. 2004; Niessing and Friedrich 2010; Vincis et al. 2012), sculpted by long-range inhibitory interactions among mitral and tufted cells (Yokoi et al. 1995; Aungst et al. 2003). In computational terms, these inhibitory interactions can be characterized in feedforward and lateral inhibition (Cavarretta et al. 2016, 2018), mediated via glomerular (GL) and granule cell (GCL) layers, respectively (Cavarretta et al. 2016, 2018). In particular, the lateral inhibition is driven by clusters of odor-responsive mitral and tufted cells (Yokoi et al. 1995), which are organized in glomerular units (GUs) (Migliore et al. 2015; Cavarretta et al. 2016, 2018).

The existing experimental protocols are not the right methods for extensive analyses of the OB. On the one hand, the scope of the electrophysiological studies is limited to small neuron set (Shusterman et al. 2011; Smear et al. 2011). On the other hand, imaging techniques enable the visualization of neuron signals over large areas of the OB but not to identify these signals at the cellular level (Abraham et al. 2004; Niessing and Friedrich 2010; Vincis et al. 2012). In the last decades, the intrinsic limitations of the experimental protocols have been overridden by large-scale computational modeling. Different models of the OB have been developed with different paradigms, reproducing specific aspects of the real system. Here we have discussed the most recent large-scale models of the OB (Yu et al. 2013; Li and Cleland 2013; Polese et al. 2014; Gilra and Bhalla 2015; Cavarretta et al. 2018), with focus on the first three-dimensional large-scale model of the OB (Cavarretta et al. 2018).

The Large-Scale Three-Dimensional Model of the Olfactory Bulb

The three-dimensional model of the OB consists of a digital reconstruction of about 10% of the real system (127 glomeruli) that replicates the physiological properties of the two largest populations of glutamatergic neurons, mitral (MC) and middle-tufted (mTC) cells, and the inhibitory circuitry in GL and GCL, along with their connectivity and glomerular organization (Fig. 1) (Migliore et al. 2014; Cavarretta et al. 2016, 2018).

The model recreates the laminar organization of the OB in a virtual three-dimensional space. The OB shape is approximated as an ellipsoid (Fig. 1a, left), where the neuronal elements take place within different laminae (Fig. 1a, right), according to the real positions in the OB. In the dorsal part, 127 glomeruli are positioned on the OB surface (Fig. 1b), replicating a real map of odor-responsive glomeruli obtained experimentally (see Vincis et al. 2012).

Specifically, the reconstruction includes mitral (MC), middle tufted (mTC), granule (GC), and deep short-axon (dSAC) cells. Biophysically detailed models of MCs and mTCs replicate their morpho-electric properties (see “[Morpho-electric Properties of Mitral- and Middle-Tufted Cells](#)”). Their morphologies fully replicate the entire dendritic arborization, in three dimensions, and were generated by a random algorithm (Fig. 1c) (see “[Generation of Realistic Mitral- and Middle-Tufted Cell Morphologies](#)”). Differently, GC and dSAC are represented with biophysically detailed “ball-and-stick” models.

The model connectivity replicates the glomerular organization that characterizes the OB. MCs and mTCs are grouped in glomeruli that receive olfactory inputs from OSNs that belong exclusively to a single genotype (Fig. 1a, right) (see “[Model of Olfactory Sensory Neuron Response](#)”), i.e., expressing the same odor receptor (Shepherd et al. 2004). The size of each glomerulus is reduced to 5 MCs and 10 mTCs. In the external plexiform layer (EPL), MCs/mTCs connect with GCs (Fig. 1a, right), making dendrodendritic reciprocal synapses with separate subsets of GCs, superficial (sGC) and deep (dGC) GCs, respectively (Geramita et al. 2016). For each connection, the MC/mTC makes a glutamatergic synapse on the GC, while this makes a GABAergic synapse on the same MC/mTC (Fig. 1a, right) (for review, see Shepherd et al. 2004). Thus, each MC and mTC in the model connects with ~700 dGCs and ~1250 sGCs, respectively.

Both the synapses in a reciprocal connection incorporate a long-term plasticity rule for odor-learning simulation (for review, see Cavarretta et al. 2016), with the consequent GC column formation and organization in GUs (Fig. 1d) (see “[Summary of Model Predictions](#)”).

Differently, the GL consists of a mathematical microcircuit that computes the net glomerular excitation conveyed onto MC/mTC tuft dendrites, as a result of the excitation conveyed from olfactory sensory neurons (OSN) (see “[Model of Olfactory Sensory Neuron Response](#)”), and inhibition conveyed from juxtaglomerular periglomerular (PG) cells (see “[Glomerular Layer](#)”) (Cavarretta et al. 2016, 2018).

Large-Scale Models of the Olfactory Bulb, Fig. 1 The three-dimensional large-scale model of the olfactory bulb (Cavarretta et al. 2018). (a) *Left*: The laminar organization replicated in the three-dimensional large-scale model of the

olfactory bulb (OB). Laminae: glomerular layer (GL), external plexiform layer (EPL), mitral cell layer (MCL), and granule cell layer (GCL). *Right*: Schematic diagram of the model connectivity in relation to the laminar

Technical Details

The model was implemented in NEURON (Hines and Carnevale 1997) and Python. The cell models comprise of multiple subcellular sections, each subdivided in multiple compartments. Simulations were parallelized with the NEURON Multisplit library (Hines et al. 2008). Synaptic connections were implemented using the NEURON Multisend protocol (Hines et al. 2011).

Morpho-electric Properties of Mitral- and Middle-Tufted Cells

The MC/mTC morphologies are randomly generated with an algorithm designed ad-hoc, which synthesizes an unlimited number of three-dimensional morphologies of MCs/mTCs (Fig. 1c), with realistic levels of morphological complexity as well as cell-to-cell variability (see “Generation of Realistic Mitral- and Middle-Tufted Cell Morphologies”).

The membrane properties are modeled with Hodgkin-Huxley equations (for review, see Hines and Carnevale 1997). In particular, the passive membrane properties are fixed in accord with previous experimental estimates (Burton and Urban 2014, 2015). For all cells, the conductance densities of ion channels are chosen to replicate firing patterns and F-I curves observed experimentally (Burton and Urban 2014; Geramita et al. 2016). In particular, in our model, MCs generate tonic firing in response to current steps (Cavarretta et al. 2016), while mTCs tendentially respond with bursting (Cavarretta et al. 2018). Moreover, the model of mTC suggests that this cell type generates rebound bursts in response to

hyperpolarizing current pulses, confirmed with our subsequent experiments (see Cavarretta et al. 2018).

Generation of Realistic Mitral- and Middle-Tufted Cell Morphologies

The algorithm for MC/mTC morphology generation is:

```
FOR each MC/mTC:
    Generate soma shape and location;
    Generate # of LD and direction of
    first segment of LD and AD;
    Create a list (L) of tip dendrites;
    ITERATE N times AND while L is not
    empty DO:
        FOR each element in L:
            test extension of a dendrite
for M times:
    generate new segment
    (direction and diam);
    IF inside the boundary:
        update L;
        break;
    IF extension fails:
        delete element from L;
    ELSE IF can bifurcate:
        generate new tips and add
to L;
    ELSE IF apical dend. is
within GCL:
        generate first segment of
TDs and add to L;
```

Abbreviations: MC, mitral cell; mTC, middle tufted cell; LD, lateral dendrites; BL, branch length; PL, path length; BO, branch order; AD, apical dendrite; GCL, granule cell layer; TD, tuft dendrites; N = 1000; M = 10.

Notably, during the generation, a driving force bends the lateral dendrites of MCs/mCs as to

Large-Scale Models of the Olfactory Bulb, Fig. 1 (continued) organization. Each lamina contains different neuron classes or neuronal elements: The GL contains periglomerular (PG) cells; the EPL contains granule (GC) cell-apical dendrites, middle-tufted (mTC) and mitral (MC) cells in the superficial and deep parts of EPL, respectively; the MCL contains MC somata; the GCL contains somata of GC and part of their dendrites; and GCs are distinguished in superficial (sGC) and deep (dGC) granule cells. (b) Locations of the 127 glomeruli in the dorsal part of the OB

reconstruction, replicating a real glomerular map obtained experimentally (see Vincis et al. 2012). MC- and mTC-lateral dendrites highly overlap within the EPL. (c) The subcellular sections of GCs (left), MCs (right, bottom half of the lamina), and mTCs (right, top half of the lamina). mTCs comprise of the same types of subcellular sections as MCs but are smaller in size (compare cells in bottom and top halves of the lamina). (d) An example of glomerular unit with GC column in the OB model, generated by odor-learning simulation

follow the shape of the OB surface (Fig. 1b–d), mimicking the characteristic curvature observed in anatomical studies.

The parameters of the algorithm are the distributions of the maximal path-length, branch length, and branching probability, estimated from full morphological reconstructions of MCs and mTCs (see Igarashi et al. 2012). A subset of these morphologies was selected as a test set for validation of the synthetic morphologies, comparing the Sholl plots and the proportions of branches versus order (for MC validation, see Migliore et al. 2014; for mTC validation, see Cavarretta et al. 2018).

Model of Olfactory Sensory Neuron Response

The time course of OSN response $S(t)$ is described with a system of ordinary differential equations:

$$S(t) = O(t)(1 - D(t)) \quad (1)$$

where

$$\begin{cases} \frac{dO}{dt} = K_O(1 - C - O) \\ \frac{dC}{dt} = K_{C_1}OC(1 - C) + K_{C_2}(1 - C) \\ \frac{dD}{dt} = K_{D_1}O(1 - D) + K_{D_2}D(1 - O) \end{cases} \quad \text{with} \\ t \in [0, T]$$

where T indicates the sniffing period (i.e., inverse of the sniffing frequency); O , C , and D are states (initial conditions: $O(0) = 0$, $C(0) = 1$, $D(0) = 0$), corresponding to *open*, *closed*, and *desensitized* states of the olfactory receptor, respectively; $K_O (=0.01 \text{ ms}^{-1})$, $K_{C_1} (=0.01 \text{ ms}^{-1})$, $K_{C_2} (=10^{-4} \text{ ms}^{-1})$, $K_{D_1} (=1.7 \cdot 10^{-4} \text{ ms}^{-1})$, and $K_{D_2} (=0.01 \text{ ms}^{-1})$ are rates.

The aggregate excitatory postsynaptic current induced in MC/mTC tuft dendrites is calculated as

$$I_{ORN}(t) = [\tilde{g} + g_{\max} GL_i(c)S(t)][V_m(t) - E_{\text{AMPA/NMDA}}]$$

where V_m is the membrane potential, $E_{\text{AMPA/NMDA}} (=0 \text{ mV})$ is the reversal potential of the synapse, $g_{\max}$ is the synaptic conductance peak, and $\tilde{g}$ is a random term.

Odor Inputs

Given an odor, $GL_i(c)$ describes the dose-response relationship for an OSN class that expresses exclusively one class of odor receptor, which conveys excitation onto a single glomerulus (for review, see Shepherd et al. 2004). The dose-response relationship depends on the odor affinity of the OSN class, described as function of odor concentration. Specifically, in our model, $GL_i(c)$ describes the peak response of an OSN, i.e., the maximum value of $S(t)$ (see Eq. 1), defined as a Hill function of odor concentration (see Cruz and Lowe 2013):

$$GL_i(c) = \frac{F_{\max}}{1 + \frac{1}{\eta_i} \left(1 + \frac{K_i}{c}\right)^n} \quad (2)$$

where $\frac{F_{\max}}{1+\eta_i}$ defines the maximum OSN response, $F_{\max}$ is the maximum activation across all odor-glomerulus pairs, η_i depends on the odor identity, K_i controls the intercept of the Hill function, and n is the cooperativity exponent.

Furthermore, odors are described as arrays of OSN inputs due to distinct sets of parameters $GL_i(c)$ (Eq. 2), defining the dose-response relationship for an odor-glomerulus pair. For sake of simplicity, $F_{\max}$, K_i , and n are chosen identical for all pairs; the values of η_i were inferred from an experimental data set of 19 natural odors (for review, see Cavarretta et al. 2016), in a way that the dose-response maxima replicate the proportions among the glomerular responses observed in the experiments (see Vincis et al. 2012).

Glomerular Layer

The glomerular microcircuit consisted of a mathematical equation set described in previous works (Cleland and Sethupathy 2006; Cleland and Linster 2012). Under the assumption that PGs modulate OSN excitation, PGs mediate feedforward inhibition on MC/mTC tuft dendrites, implementing *olfactory input normalization* and the *nontopographical contrast enhancement* (see “[Learning-Dependent Processing of Natural Odors](#)”). Given the glomerular excitation $GL_i(c)$ (see Eq. 2), the normalized input $GL_i^{\text{norm}}(c)$ was calculated as

$$GL_i^{\text{norm}}(c) = \begin{cases} GL_i(c) - \bar{GL}_i(c), & \text{if } GL_i(c) - \bar{GL}_i(c) > 0 \\ 0, & \text{otherwise} \end{cases}$$

with $\bar{GL}_i(c) = \frac{1}{N} \sum GL_i(c)$, while contrast-enhanced odor input $GL_i^{\text{CE}}(c)$ was calculated as

$$GL_i^{\text{CE}}(c) = \begin{cases} GL_i^{\text{norm}} - \text{PG}[GL_i^{\text{norm}}(c)] - \bar{GL}_i(c), & \text{if } GL_i^{\text{norm}} - \text{PG}[GL_i^{\text{norm}}(c)] > 0 \\ 0, & \text{otherwise} \end{cases}$$

$$\text{with } \text{PG}(x) = \begin{cases} \frac{0.6}{1 + 0.01 \left(\frac{1}{x} - 1 \right)}, & \text{if } x > 0 \\ 0, & \text{otherwise} \end{cases},$$

$\text{PG}(x)$ describes the intraglomerular. Therefore, $GL_i^{\text{CE}}(c)$ returns the net odor input, i.e., net excitation, conveyed on MC/mTC tuft dendrites.

Summary of Model Predictions

The three-dimensional morphologies of MCs and mTCs constitute a centerpiece of this model of the OB. Their lateral dendrites have anatomically plausible extent so that they likely replicate the breadth of glomerular dendritic fields with physiological levels of overlap. Importantly, the overlap correlates with the number of GCs that are shared between GUs. In our simulations, odor learning generates the sparse and segregated organization in GC columns (Fig. 1d) (see Willhite et al. 2006), with realistic shape, size, and spatial distribution (Cavarretta et al. 2016). Taken together, these features regulate the spatial spreading as well as the strength of lateral inhibition (Cavarretta et al. 2018), and these are a fundamental aspects for the realistic simulation of the lateral interactions between GUs.

Odor Learning, Granule Cell Column Formation, and Organization in Glomerular Unit

The model provides several hints of the dynamics underlying GC column formation (Willhite et al. 2006), which can be summarized in four steps:

- (i) Odors evoke action potentials (APs) in MCs/mTCs that back-propagate along the lateral dendrites.
- (ii) At sufficiently high rate, back-propagating APs activate long-term potentiation in the reciprocal

connections between MCs/mTCs and GCs (MTC-to-GC, GC-to-MTC) (see above).

- (iii) Once the excitatory synapses (MC/mTC-to-GC) are sufficiently potentiated, the APs (back-propagating along MC-/mTC-lateral dendrite) elicit APs in the GCs, activating long-term potentiation in the inhibitory synapses (GC-to-MTC).
- (iv) The inhibitory synapses dampen AP back-propagation in MC-/mTC-lateral dendrites, reducing the firing rate locally, and causing long-term depression in the distal synapses.

Finally, the strongest reciprocal connections remain near the MC/mTC somata, forming cylindrical clusters beneath the odor-responsive glomeruli (Fig. 1a). Therefore, MCs, mTCs, and GCs that are functionally related to a glomerulus form a glomerular unit (GU).

Lateral Interactions Between Glomerular Units During Odor Learning

Under the assumption that GUs interact via GC columns during learning (Migliore et al. 2015), the model suggests that these interactions might promote or hinder GC column formation, affecting breadth and definition (i.e., GC density) of GC columns. The efficacy of these interactions depends on the odor-learning order (i.e., non-commutativity) and decreases with the distance between the interacting glomeruli.

Learning-Dependent Processing of Natural Odors

The model suggests that a learning-dependent dynamic underlies OB processing of natural odors (Cavarretta et al. 2016), showing that it is

optimal after formation of multiple and sparse GC columns (i.e., real anatomical pattern; see Willhite et al. 2006). Specifically, the GL circuit operates sparsely and stabilizes odor representation across different concentrations, decorrelating the spatial representations evoked by different odors, while the effect of lateral inhibition, conveyed via GCL, furthers this decorrelation over time.

Two Parallel Pathways for Odor Signaling Within the Olfactory Bulb

The model makes a functional distinction between the two parallel pathways of the OB due to MCs and mTCs (Cavarretta et al. 2018). In brief, the model suggests that:

- (i) mTCs of different GUs increase their spike synchrony in response to shared GC inputs, while spike rate decreases in MCs with high numbers of GC inputs.
- (ii) MCs and mTCs are controlled by similar computations via GL, while they are functionally separated in GCL, i.e., connecting with different subtypes of GCs.
- (iii) dSAC inhibition organizes GUs into larger entities termed “glomerular unit clusters,” where GC columns mediate inhibition within but not between GU clusters.

Spine Relocation in Adult-Born Granule Cell

Experiments *in vivo* revealed a novel form of fast activity-dependent synaptic plasticity, in which mature spines (3–8%) of adult-born GCs relocate from inactive to active MC dendrites (Breton-Provencher et al. 2016). The model suggested that spine relocations, despite their low percentage (3–6%), increased the synchronization between GUs, thereby resulting in a faster mechanism for fast oscillation generation.

Other Large-Scale Models of the Olfactory Bulb

Polese et al. (2014) developed a model of the OB that included mitral (MC), external tufted (ET),

periglomerular (PG), and superficial short-axon (sSA) cells. The cells were implemented as ball-and-stick models, whose intrinsic properties were described with Izhikevich’s equations. The authors analyzed the effects of feedforward inhibition, on the OB output, and suggested that odor identity and intensity are separately encoded in MCs and ETs, respectively.

Li and Cleland (2013) developed a model including 25 glomeruli, 1 MC per glomerulus, 25 PGs, and 100 GCs. The cells were implemented as oligocompartmental models that included one subcellular section of each type, whose intrinsic properties were described by Hodgkin and Huxley equations (Hodgkin and Huxley 1952). The authors suggested the effects of nicotinic and muscarinic modulations as: (i) Nicotinic modulation, operating in the GL, sharpens the MC-receptive fields, controlling the average firing rate, and decorrelating the representations between similar odors; (ii) muscarinic modulation, operating in the GCL, increases spike synchrony and gamma oscillations in MCs, without affecting the firing rate; and (iii) a combination of nicotinic and muscarinic modulations produces an even sharper odor tuning than either modulation alone.

Gilra and Bhalla (2015) developed a model based on a Multiscale Object Oriented Simulation Environment, Python, and NeuroML. The model included 3 glomeruli, 2 MCs per glomerulus, 1000 PGs, and ~1200 GCs. The cells were implemented as biophysically detailed multicompartmental models, whose intrinsic properties were described by Hodgkin-Huxley equations (Hodgkin and Huxley 1952). The authors studied the effects of lateral inhibition between MCs, under the assumption that intraglomerular lateral inhibition can be conveyed via GCs. However, this contradicts experimental evidence that GCs do not make multiple synapses with MTCs of the same glomerulus (Kim et al. 2011). Together, the model suggested that, over short ranges of odor concentration, MC response to odor mixtures is a linear summation of response profiles evoked by the individual odor components.

Large-Scale Neural Networks: Vision

Hugh R. Wilson

Center for Vision Research, York University,
Toronto, ON, Canada

Synonyms

Excitatory and inhibitory networks; Spike-rate neural networks; Wilson-Cowan equations

Definition

The visual system is the largest single sensory system in the brain, comprising approximately 40% of the entire cerebral cortex. Computational modeling of visual functions accordingly requires large-scale neural networks that are computationally efficient. Such networks invariably provide a mathematical description of neurons at the spike-rate level, as describing neurons at the level of individual spikes or action potentials is too computationally expensive. Despite using spike-rate equations, large-scale neural networks in vision can effectively incorporate effects of modulatory neurotransmitters, spike-rate adaptation, and other processes known to be critical for understanding visual system function.

Detailed Description

Neurons are most accurately described by the Hodgkin-Huxley equations (Hodgkin and Huxley 1952) and their subsequent elaborations. The four Hodgkin-Huxley equations describe the electrical potential across the membrane of a single neuron and accurately reproduce the shape of each spike or action potential. As each action potential is only about 1.0 msec in duration, simulations at this level of detail invariably require very small time steps for their implementation and thus are very computationally expensive. For large-scale network simulations, therefore, neurons are

frequently described at the level of spike rates. This enables each neuron to be described by just one equation rather than four and increases the size of computational time steps by more than an order of magnitude. Thus, for any amount of computational power, a network of spike-rate neurons can be at least 100 times larger than a network of Hodgkin-Huxley neurons (Wilson 1999b). Furthermore, the simplification inherent in spike-rate equations makes them optimal for mathematical analysis.

Before proceeding, it should be acknowledged that there is also an intermediate level of neuronal description that has recently been developed (Izhikevich 2003; Wilson 1999a). These models are simpler and computationally faster than Hodgkin-Huxley, and they also produce individual action potentials. Thus, they are useful for studying networks of neurons exhibiting intrinsic bursting and other complex firing properties. However, further discussion of these models is beyond the scope of this article.

Spike-Rate Equations

One of the first and most popular formulations of spike-rate dynamics are the Wilson-Cowan equations (Wilson and Cowan 1972, 1973). These equations utilize a sigmoid nonlinearity, S , that converts the postsynaptic potential, PSP , into a mean spike rate R :

$$\tau \frac{dR}{dt} = -R + S(PSP - gH) \quad (1)$$

Here τ represents the exponential rate at which R approaches the asymptotic firing rate defined by $S(PSP)$. As τ is related to the time course of postsynaptic potentials spreading along dendrites to the nerve cell body, values in the range of 10–20 msec. are generally appropriate. This represents an enormous improvement in computational efficiency relative to Hodgkin-Huxley simulations. Finally, the variable H represents a hyperpolarizing, self-adaptation function that will be described in the context of binocular rivalry below.

The sigmoid nonlinearity $S(x)$ is simply an S-shaped function such that (a) the slope $dS/dx \geq 0$, (b) there is a single point at which the slope is a maximum, and (c) dS/dx decreases monotonically above and below the point of maximum slope. Frequently used functions satisfying these criteria are:

$$S(x) = \frac{1}{1 + \exp(-a(x - \theta))}$$

$$S(x) = \begin{cases} \frac{(x - \theta)}{1 + (x - \theta)^{0.8}} & x \geq \theta \\ 0 & x < \theta \end{cases} \quad (2)$$

where θ is related to the neuronal threshold. The first of these is the logistic curve, which was used in the original Wilson-Cowan equations (Wilson and Cowan 1972) and is plotted in blue in the figure below. The second (red curve below) is a more recent function with a sharp threshold at $x = \theta$ that was introduced to describe dynamics of binocular rivalry (Wilson 2007). It is related to the Naka-Rushton (Naka and Rushton 1966) function (also called a Hill function), except that it asymptotically approaches $(x - \theta)^{0.2}$ rather than a constant value for large x . The exact shape of $S(x)$ only affects the nonlinear dynamics of large-scale networks quantitatively; the qualitative dynamics remain the same. The key observation is that a sigmoid function can be intersected by a straight line in either one or three points only. These possibilities determine the bifurcation structure of the network dynamics. For example, with three intersections, two asymptotically stable and one unstable, short-term memory states and hysteresis occur. With only one unstable state, limit cycle oscillations arise (Wilson 1999b).

The postsynaptic potential can generally be written as a weighted sum of excitatory inputs from other neurons along with subtractive inhibition:

$$PSP(t) = \sum_k w_k E_k(t) - \sum_m a_m I_m(t) \quad (3)$$

where $E_k(t)$ are firing rates of excitatory neurons with synaptic weights w_k , and $I_m(t)$ are firing rates of inhibitory neurons with synaptic weights a_m .

If appropriate, divisive inhibition can also be included.

Finally, the Wilson-Cowan equations incorporate separate arrays of excitatory and inhibitory neurons, which interact via the postsynaptic potentials in Eq. 3. Recurrent excitation and recurrent inhibition are generally described as Gaussian functions of distance, with inhibition having a wider spatial spread than excitation.

Applications to Vision

The original application of the Wilson-Cowan equations to large-scale visual phenomena consisted of a one-dimensional network comprised of a line of spatially interacting excitatory (E) and inhibitory (I) neurons. With short-range recurrent excitation and longer-range inhibition, multiple dynamic regimes emerged depending on relative excitatory and inhibitory synaptic strengths. Among these was a spatially localized short-term memory that encoded the position of a brief recent stimulus. These dynamics provide a nonlinear instantiation of the more recently introduced concept of a line attractor for eye position memory (Seung 1996). A second dynamic regime with weakened inhibition leads to traveling waves of neural activity, such as those experienced in migraine auras (Wilson and Cowan 1973).

Ermentrout and colleagues have shown that two-dimensional Wilson-Cowan networks can explain the major examples of geometric visual hallucinations induced by drugs (Ermentrout and Cowan 1979). These hallucinations include concentric circles, radial spokes, checkerboards, and spirals. Their network employed two-dimensional Gaussian short-range excitation balanced with longer-range recurrent inhibition. The key to reproducing perceived visual hallucinations was the pattern of asymptotically stable spatial steady states which were transformed into visual coordinates via the retino-cortical complex logarithmic mapping (see ► “Flicker-Induced Phosphenes”). This work was extended to encompass virtually all geometric visual hallucinations by introducing groups of orientation-selective neurons and reciprocal excitatory connectivity between collinear neurons with

the same preferred orientation (Bressloff et al. 2001). The introduction of collinear facilitation makes this large-scale network into a much more accurate model of primate visual cortex.

A further embellishment of Wilson-Cowan dynamics has proved successful at describing many aspects of binocular rivalry (Wilson 2007). The key is the introduction of very slow neuronal fatigue, which is known to occur in excitatory monkey and human cortical neurons as a result of hyperpolarizing Ca^{++} -mediated K^{+} currents with time constants of up to several seconds (Sanchez-Vives et al. 2000). A self-adaptation variable, H , was incorporated into spike-rate dynamics by introducing a simple additional equation for each neuron:

$$\tau_H \frac{dH}{dt} = -H + R \quad (4)$$

where τ_H is in the range 900–1,500 ms. This equation operates in conjunction with Eq. 1 to generate self-adaptation. Two spatial arrays of mutually inhibitory neurons incorporating such self-adaptation can reproduce the oscillations perceived in binocular rivalry. Typically, a noise term is added to the equations to explain the stochastic nature of rivalry. Rivalry has also been shown to generate spreading dominance waves (Wilson et al. 2001), and these waves can be explained by competing spatial arrays of spike-rate neurons with appropriate synaptic connectivity. Mathematical analysis of a continuum version of the Wilson-Cowan equations has elucidated the details of dominance wave propagation and produced estimates of wave speed as a function of network parameters (Bressloff and Webber 2012).

Conclusion

Wilson-Cowan equations are very effective at simulating and analyzing large neural networks for understanding visual and other neural functions. Synaptic connectivity can be specialized based on the anatomy and physiology of different cortical areas, and ion currents with different time courses can be introduced to allow for neural

adaptation. Hebbian learning with symmetric excitatory connections can also be introduced to produce Hopfield networks for long-term associative pattern memory (Hopfield 1984). Finally, temporary synaptic facilitation of network connections can account for short-term perceptual memory in binocular rivalry (Wilson 2007). The only areas in which spike-rate neural networks cannot be used are those in which precision of individual spike timing or spike synchronization is critical. One example would be simulations of auditory localization, in which extremely small differences in the arrival time of spikes from the two ears are crucial.

Definition

LGN models refer to mathematical models for the activity of neurons (relay cells and interneurons) in the lateral geniculate nucleus (LGN) of the thalamus. The LGN is positioned between the retina and the primary visual cortex in the early visual pathway in mammals.

Detailed Description

Overview of LGN Circuit

The lateral geniculate nucleus (LGN) acts as a gateway for visual signals to reach cortex. It receives driving input from retinal ganglion cells (RGCs) and modulatory input from the cortex, the thalamic reticular nucleus (TRN), and the brainstem. The principal cells in the LGN, the thalamocortical relay cells (RCs), transmit visual information to the cortex. They constitute about 75–80% of the cells in the

nucleus, while the remaining 20–25% are intrageniculate interneurons (INs). The RCs receive synaptic inputs from a variety of sources: direct *feedforward excitation* from RGCs; indirect *feedforward inhibition* via the INs, which in turn receive excitatory input from RGCs; *feedback inhibition* from the TRN; and *feedback excitation* from primary visual cortex. Both the IN and TRN cells further receive excitatory feedback from the cortex opening up the possibility for *feedback inhibition* of RCs involving the entire thalamocortical loop. For reviews of the neurobiology of LGN, see Ghodrati et al. (2017) and Sherman and Guillery (2001).

LGN models range from biophysically detailed models aiming to explain distinct features of the signaling properties of single neurons to more abstract models aiming to explain the responses of neurons to visual stimuli and the overall function of the LGN circuit.

Types of Mathematical Models

Mathematical models in neuroscience can be categorized into three types: mechanistic, descriptive, and interpretive (Dayan and Abbott 2001). *Mechanistic* (physics-type) models aim to find out how properties of the system arise from the physical properties of the underlying parts. *Descriptive* (statistical) models are used to summarize experimental data or encapsulate key properties compactly. *Interpretive* (normative) models instead aim to model the functional roles of neural system, for example, relating neuronal responses to the task of processing useful visual information for the animal.

Single Neuron Models

Relay Cells (RCs)

Numerous mechanistic models for RCs based on the cable equation description of neurons have been developed and explored. They differ in the choice of neuronal morphology (single compartment/multicompartment) and included ion conductances. With some right one may distinguish between models tailored to explore specific aspects of RC activity and more general-purpose models that aim to capture a series of RC functions.

Examples of the former type are the investigation of the impact of dendritic morphology on integration of synaptic inputs in models with passive (Bloomfield and Sherman 1989; Briska et al. 2003) and active (Connelly et al. 2016a; Perreault and Raastad 2006) dendrites. Other examples are single-compartment models that explore how a large (~10) number of active (Hodgkin-Huxley style) conductances affect the somatic response properties (McCormick and Huguenard 1992) or control the resting potential and subthreshold dynamics (Amarillo et al. 2014). Many models have focused on the ability of RCs to exhibit two different firing modes (tonic and bursting), a key feature of RCs (Sherman and Guillery 2001). The somatic subthreshold oscillations underlying burst firing in RCs have been studied both in single-compartment (Amarillo et al. 2014; Destexhe et al. 1993; Huguenard and McCormick 1992; Toth and Crunelli 1992; Zeldenrust et al. 2013) and multicompartment models (Destexhe et al. 1998; Wei et al. 2011). Also, different aspects of the suprathreshold bursting/tonic firing properties have been studied both in single-compartment (Broicher et al. 2007; Deleuze et al. 2012) and multicompartment models (Connelly et al. 2015; Destexhe et al. 1998; Zomorodi et al. 2008).

The most comprehensive models are multicompartmental models based on anatomically reconstructed dendritic morphologies and incorporate synaptic input and several active conductances both in the soma and in the dendrites (Antal et al. 1996; Connelly et al. 2015, 2016a; Emri et al. 2000, 2003; Rhodes and Llinas 2005). The perhaps most general of these is a multipurpose model developed to capture a broad range of RC response properties (Rhodes and Llinas 2005). Some of the RC models also explicitly include intracellular calcium dynamics (Connelly et al. 2015, 2016a; Destexhe et al. 1993, 1998; Rhodes and Llinas 2005; Wei et al. 2011; Zomorodi et al. 2008).

Leaky integrate-and-fire (LIF) type models, avoiding the computationally expensive calculation of the action potential generation process itself, are commonly used by computational neuroscientists, and a single-compartment *leaky integrate-and-fire-or-burst* (LIFB) model has been

developed to capture the dual tonic-burst action of RCs (Lesica and Stanley 2004; Smith et al. 2000). Further, descriptive models capturing salient properties of RC neuronal dynamics have been derived by means of techniques from nonlinear dynamics (Rose and Hindmarsh 1985, 1989a, b, c).

Direct fitting of neuron models to in vivo experimental data has been rare. However, the *leaky integrate-and-fire* model has been tuned to model the transmission of spikes at the connection between RGCs and RCs in cat (Casti et al. 2008). Along the same line, a so-called spike response model (Gerstner and Kistler 2002) was fitted to corresponding data from macaque (Carandini et al. 2007). Both models were later found to be well accounted for by simple firing-rate models (Heiberg et al. 2013).

Interneurons (INs)

In addition to the tonic/burst spiking feature also seen in RCs, INs also exhibit dendrodendritic inhibition (on RCs) through specialized triadic synapses (Sherman and Guillery 2001). Despite (or maybe because of) their likely more complicated action, fewer models have been developed for INs than RCs. Some models have investigated signal propagation in the elaborate dendritic structure of INs in the case of passive (Bloomfield and Sherman 1989; Briska et al. 2003) or active (Allken et al. 2014; Casale and McCormick 2011; Perreault and Raastad 2006) dendrites. One simplified model explores the differences in burst firing between INs and RCs (Broicher et al. 2007). A range of IN somatic response properties is captured in two, relatively general, multicompartmental models with realistic morphologies (Halmes et al. 2011; Zhu et al. 1999), and the most comprehensive of these two also includes active dendritic conductances (Halmes et al. 2011). Some of the IN models include intracellular calcium dynamics (Allken et al. 2014; Halmes et al. 2011; Zhu et al. 1999).

Descriptive Models for Response to Visual Stimuli

Starting with the introduction in the 1960s of the *difference-of-Gaussians* (DOG) model (Rodieck 1965) to describe responses in retinal neurons

(RGCs), there has been a long tradition in using descriptive filter models to account for responses to visual stimuli of neurons in the early visual pathway (retina, LGN, primary visual cortex; Chap. 2 in Dayan and Abbott (2001)). In this model the receptive-field function $D(r, t)$ (also called point-spread function) describing the theoretical response of a neuron to a flashing point stimulus (briefly on at time $t = 0$) a distance r from the receptive-field center is assumed (i) spatiotemporally separable, i.e., $D(r, t) = f(t)g(r)$ with (ii) the spatial part given as a difference between two Gaussian functions:

$$g(r) = A_c e^{-r^2/\sigma_c^2} - A_s e^{-r^2/\sigma_s^2}$$

Here the first term is referred to as the *center* contribution, while the second term is referred to as the *surround* contribution.

In applications to RCs in LGN, a generalized receptive-field function where the center and surround terms have different temporal profiles has typically been used (Chap. 2 in Dayan and Abbott (2001)), i.e.:

$$D(r, t) = g_c(r)f_c(t) - g_s(r)f_s(t)$$

Here the spatial functions $g_c(r)$ and $g_s(r)$ have been modeled as Gaussian functions, and the temporal profiles, represented by the functions $f_c(t)$ and $f_s(t)$, have been set to have the surround contribution lagging behind the center contribution (Dawis et al. 1984; Kaplan et al. 1979). While the temporal functions $f_c(t)$ and $f_s(t)$ have been chosen to have the same functional form and to be distinguished only by the choice of function parameters, different choices of biphasic functions have been used to model them (Allen and Freeman 2006; Cai et al. 1997; Dayan and Abbott 2001). Also a variant with a nonlinear suppressive field acting as a response normalization has been used (Bonin et al. 2004).

RC receptive-field functions with $D(r, t)$ given as a sum of three spatiotemporally separable components, two components representing *transient* responses to stimuli onset and one component representing the *sustained* response, have also been developed (Einevoll et al. 2011).

The above receptive-field functions predict time-resolved firing rates suitable for comparison with poststimulus time histograms (PSTHs) (Dayan and Abbott 2001), but such models have also been used to generate spike trains assuming specific spike-train statistics (Gazères et al. 1998). So-called *generalized linear models* (GLMs), determined by fitting such spike-generating descriptive models to experimental data, have also been employed in the analysis of RC data (Babadi et al. 2010).

Mechanistic Network Models

Most mechanistic network models of the early visual pathway have focused on the response of neurons in the primary visual cortex, the station after the LGN. In such models the modification of retinal signals by the LGN has often been neglected altogether or been included in a simplified fashion. Here only models focusing on the response of LGN neurons will be described.

One class of model simulations has considered comprehensive two-dimensional grids of spiking neurons representing a part of the visual field. One class of studies has used simplified LIF model neurons, mostly only explicitly modeling RCs (Connelly et al. 2016b; Kirkland and Gerstein 1998; Köhn and Wörgötter 1996; Wörgötter et al. 1998) but also both RCs and INs (Wielaard and Sajda 2007). In these studies, the network received spike-train inputs from grids of RGCs and sometimes also feedback from cortical cells (Kirkland and Gerstein 1998; Köhn and Wörgötter 1996; Wörgötter et al. 1998). Similar studies have also been performed with firing-rate point-neuron models replacing the spiking neurons (Einevoll and Heggelund 2000; Hayot and Tranchina 2001; Yousif and Denham 2007).

Networks based on single-compartment Hodgkin-Huxley-style models of LGN neurons have also been studied (Behuret et al. 2013; Kosmidis 2002; Rogala et al. 2013). Lately such network models have also incorporated multi-compartment INs exhibiting both axonal and triadic inhibition, both without (Heiberg et al. 2016) and including cortical feedback (Martinez-Canada et al. 2018).

Another line of work has investigated more generic questions about the properties of networks of LIFB neurons representing RC neurons interacting with neurons in the thalamic reticular nucleus (TRN), both a minimal model consisting of a pair of single RC and TRN neurons (Babadi 2005) and a more extended model where each population is represented by one-dimensional grids of LIFBs (Huertas et al. 2005). Such LIFB networks have also been investigated with a *population density approach*, both for a population of RC LIFBs by itself (Casti et al. 2002) and for coupled populations of RCs and TRN LIFBs (Huertas and Smith 2006).

Finally, both neural mass models (Norheim et al. 2012) and neural field models (Einevoll and Plesser 2002, 2012) have been developed to model the processing of visual signals by LGN circuit. In particular, the so-called *extended DOG* (*eDOG*) model combines the descriptive DOG model with a mechanistic model for the effect of cortical feedback to produce a closed-form expression for the spatiotemporal receptive-field function (Einevoll and Plesser 2012; Nirody 2014). A Python simulator, pyLGN, has been implemented for easy exploration of the eDOG model (Mobarhan et al. 2018).

Numerous network models have been developed to investigate the role of thalamocortical oscillations, typically without including sensory input in the model. We do not cover these models here and rather refer the interested reader to Refs. (Barardi et al. 2016; Destexhe and Sejnowski 2001). Also, models of the interactions between the LGN and the TRN, or single-cell models of TRN cells, were not covered here, but see, e.g., Destexhe and Sejnowski (2001) and Willis et al. (2015).

Interpretive Models

Interpretive models for the possible functional role of LGN are fewer. One study showed why both *lagged* and *non-lagged* RCs, which are observed experimentally, could be useful for obtaining efficient visual representations (Dong 1995). Another study in the same vein argued why the observed biphasic temporal response of RCs could reflect *predictive coding* (Jehee and Ballard 2009). A third study showed how the

LGN cells may form a resampled map of visual space to facilitate detection of stimulus position (Martinez et al. 2014).

Leech Local Bend: Neural Coding of Touch Location

John E. Lewis

Department of Biology, University of Ottawa,
Ottawa, ON, Canada

Definition

In response to a light touch, the medicinal leech bends away from the touched site, a behavior called the local bend. Using a three-layer neuronal network comprising mechanosensory neurons, interneurons, and motor neurons, the leech encodes touch location and coordinates muscle contraction to produce the appropriately directed bend.

Detailed Description

Background

Our understanding of neural coding has benefited significantly from the study of well-defined behaviors produced by relatively small nervous systems. In terms of neural underpinnings, more of such behaviors are understood in the medicinal leech than in any other system (Kristan et al. 2005). This is due, in part, to the leech's segmented nervous system, which comprises 21 ganglia connected in series to form a nerve cord, with head and tail ganglia at either end.

Leech Local Bend: Neural Coding of Touch Location, Fig. 1 (a) Schematic of a cross-sectional view of the leech tubular body illustrating the local bend problem. Touching the skin at a location indicated by the green arrow (the

touch angle) produces a bend directed away from the touched site, indicated by the red dot (the bend angle). (b) The local bend network comprising three layers of neurons (see text)

The leech produces “whole-body” behaviors (such as swimming and crawling) that involve coordination between neurons in all ganglia, as well as “local” behaviors (such as local bending) that are generated by neurons in a single ganglion. Other behaviors (such as heartbeat control) involve several ganglia. The leech nervous system is also very amenable to neurophysiological study: the nerve cord (or any number of ganglia) can be isolated in a dish and still produce the motor patterns associated with the different behaviors. In addition, each segmental ganglion contains about 400 neurons, many of them identifiable from animal to animal. So, one can characterize the activity of the same neuron from different ganglia or in different animals to determine how the underlying networks produce each motor pattern and make choices between behaviors (Kristan et al. 2005; Kristan and French 2010).

The Leech Local Bend

A light touch to the skin of a leech results in a local bend, a subtle bending of the body away from the touched site (Kristan et al. 1995; Lewis 1999). The behavior is mediated within a single segment of the leech tubular body. It is convenient to express both the touch location and the bend direction by an angle. In other words, the location

of a touch at some point around the perimeter of the cross section of a single body segment is described by an angle (θ_{touch}) from 0° to 360° (Fig. 1a; green line). Similarly, the bend angle (ϕ_{bend}) can be represented by the point along the body perimeter at which the motor response is maximal (Fig. 1a; red line). In this way, it is clear that the local bend involves a simple directional input–output relationship, with a “perfect” response indicated by $\phi_{\text{bend}} = \theta_{\text{touch}}$.

The local bend network controls this directed behavior. This network contains about 50 neurons organized in three distinct neuronal layers (Fig. 1b). **The first layer** comprises the sensory inputs: four mechanosensory P neurons encode the location of touch on the skin. **The third layer** comprises the motor output: four groups of longitudinal motor neurons (about 20 neurons in total) control the length of longitudinal muscle (shortening near the touch and lengthening opposite the touch produce the appropriate bend). **The second layer** consists of a population of about 25 interneurons, with 17 identified so far (Lockery and Kristan 1990).

To produce the appropriately directed bend, the local bend network must solve a number of problems. First, touch location must be represented in the firing patterns of the P neurons. Second, the layer of interneurons must form a new representation of touch location based on P neuron inputs. Third, this information must be transferred to the

motor neurons, whose relative activity and innervation of the body wall muscle, along with the biomechanics, determine bend direction.

Neuronal Population Coding

Population coding has been implicated in a wide variety of neural systems. In such codes, information is distributed over a population of neurons, rather than in the activity of a single neuron. Coding the intensity of a sensory stimulus (e.g., pressure of a light touch) often involves a single neuron code; the firing rate of the associated receptor neuron increases monotonically with stimulus intensity. On the other hand, the representation of color in the visual system is an example of population coding. Here, color is encoded by the relative activation of different classes of photoreceptors tuned to distinct wavelengths of light (e.g., red, green, and blue). While different photoreceptor classes are tuned to their “preferred” wavelengths, they also respond (albeit to a lesser extent) to a range of wavelengths; this range is large enough that the tuning curves for each class overlap. So for a given wavelength, each class of photoreceptor will be activated to varying levels. Therefore, the activity of a single photoreceptor class does not alone provide sufficient information for the range of color

sensitivities. Rather, activity across the population of broadly tuned photoreceptors is necessary. Such broad tuning is one hallmark of population coding.

Neuronal networks can implement a variety of population codes (see ► [“Computation with Population Codes”](#)). To show that a particular population code is implemented in a given system, a number of experimental tests are necessary. First, a measure of population activity that is based on the proposed code should be correlated with the sensory input (or behavioral output). Second, systematic manipulation of the population activity should have an effect that is predicted by that particular code. And third, the network properties required to implement or “read out” the population code must be present.

A Population Code for Touch Location

The local bend network provides a fruitful context in which to evaluate a population code. With only four P neurons, one can record the intracellular activity from all sensory inputs and measure bend direction on a trial-by-trial basis (Lewis and Kristan 1998a).

P neuron responses are characterized by their tuning curves (Fig. 2), which can be quantified by the number of spikes elicited by stimuli at

Leech Local Bend: Neural Coding of Touch Location, Fig. 2 The tuning curves for the mechanosensory P neurons. Response is expressed by the total spike count (normalized to maximum) as a function of touch angle. The

mean response is given by a solid blue line (different shade for each of the four P neurons), and for the case of P₂, the dotted lines indicate one standard deviation from the mean

different touch angles, θ_{touch} . The resulting tuning curves are cosine shaped, revealing broad tuning, with the peaks (or preferred touch angles θ_{P_i}) evenly distributed around the body perimeter. This suggests that touch angle is represented in a 2-D coordinate system with two orthogonal axes given by unit vectors pointing in the directions of the preferred touch angles (Fig. 3a). Four neurons are required because the spike count cannot be negative, so a pair of neurons, with preferred angles 180° apart, forms a single axis (i.e., P_1 – P_3 for one axis and P_2 – P_4 for the other). For a given touch angle, two P neurons are usually activated, one associated with each of the two axes (Fig. 3b). This pair of spike counts represents the touch angle just like an (x, y) pair in a Cartesian coordinate system. Such a representation is a 2-D version (four neurons) of the **population vector**, a population code first used to describe the neural coding of **reaching movements**. More generally, the population vector is the vector sum of all neurons' preferred angles, weighted by their respective spike counts; in other words, each spike produced by a given neuron is a “vote” for that neuron's preferred angle (see ► [“Computation with Population Codes”](#)). Figure 3b illustrates a simple example of how the population vector works on a single trial. A touch angle of 30° elicits 12 spikes in P_1 and 4 spikes in P_4 ; P_2

and P_3 are silent (Fig. 3b, insets). The magnitude of the vector in the direction of θ_{P_1} is 12 (P_1 – P_3) and that in the direction of θ_{P_2} is –4 (P_2 – P_4). The red dot shows the point (12, –4) in this coordinate system, with the touch angle predicted by the population vector ($\phi_{P\text{-vector}}$) given by the direction of the resultant vector.

While such cosine-tuning curves are suggestive, their presence does not necessarily indicate that the local bend network uses a population vector code. The next step is to compare the behavioral output (ϕ_{bend}) to the P neuron population vector prediction ($\phi_{P\text{-vector}}$). It is important to consider the variability of P neuron firing: while the mean spike counts of P neurons clearly indicate cosine tuning, the standard deviation of these responses is about 25% of the mean value (Lewis and Kristan 1998b). This is illustrated in Fig. 2 by the dotted lines, showing one standard deviation above and below the mean response of one P neuron. Taking this variability into account, the population vector estimate of touch angle has a root-mean-square error less than 3% (about 11°). If the leech uses a population vector code, then the bend direction cannot be any more accurate than this – the accuracy of the behavior is limited by the variability of the sensory input. While early experiments suggested bending angle to be within about 8% of touch angle (Lewis and Kristan

Leech Local Bend: Neural Coding of Touch Location, Fig. 3 (a) Preferred touch angles for each P neuron (i.e., touch angle of maximum response) are shown in the body coordinates introduced in Fig. 1a. (b) Example trial for a given touch angle (green). P neuron spike trains are

shown schematically in the insets. Each preferred angle is weighted by the associated spike count, and the angle of the resultant vector (P vector in red) is the touch angle predicted by the population vector (see text)

1998c), subsequent studies using more sophisticated measures have revealed behavioral accuracies closer to 4% (Zoccolan et al. 2002; Baca et al. 2005). Even so, a population vector based on P neuron spike counts is still sufficient to explain local bend accuracy, and thus, a more complicated algorithm, for example, involving the details of spike timing, is not necessary.

Further, one can also compare bend angle and P neuron population vector estimates on a trial-by-trial basis. As just discussed, the variability in P neuron firing leads to variability in the P neuron population vector. On a given trial however, one P neuron may fire more than average so that the population vector would be biased towards that neuron's preferred touch angle. Similarly, systematically manipulating the activity of one P neuron (using intracellular current injection) would also bias the population vector estimate. When such experiments were performed, the bend angle was biased in the predicted direction, showing a significant correlation between $\phi_{\text{P-vector}}$ and ϕ_{bend} (Lewis and Kristan 1998a).

These observations suggest that the local bend network uses a population vector code, but do not explain how the computation is performed. For this, we must consider the synaptic connections between network layers. This is no easy task. Although it is possible to use high-throughput techniques to estimate network connectivity, ultimately we need to record from many pairs of neurons. This was possible, although extremely difficult, in the local bend network (Lockery and Kristan 1990). The data showed that the population of local bend interneurons forms a distributed representation of the P neuron inputs. In other words, each interneuron receives inputs from multiple P neurons, but to varying extents. The result is that the interneurons, like the P neurons, are broadly tuned to touch angle, with their preferred angles distributed around the body perimeter (Lewis 1999). More specifically, the synaptic strength from a single P neuron to a given interneuron is related to the cosine of the difference in their preferred angles. This is exactly the type of connectivity that results in the accurate transfer of information encoded in a population vector (Abbott 1998).

Outlook

Despite the extensive support for this population vector strategy in the local bend network, subsequent studies have revealed more complexity at both the sensory and behavioral levels. Although the simple P neuron spike count is sufficient to account for the behavior, the precise timing of the spikes provides additional information. In fact, the relative latency between two P neurons more accurately represents touch angle than does the raw spike count (Thomson and Kristan 2006). It appears that the local bend network uses this information, but to what extent is not clear. Nonetheless, P neuron spike counts are sufficient to explain behavioral accuracy, suggesting that additional information is lost through the network layers. The details of information transfer through the local bend network are also unclear. We know however that the network includes a mechanism for gain control, allowing a robust bending response over a large range of touch intensities. This gain control is mediated by global inhibition that is balanced with the level of sensory excitation (Baca et al. 2008). Additional information loss in the context of local bending may be due to the multifunctional nature of many neurons in the ganglion. The same neurons are commonly used for different behaviors (Briggman and Kristan 2008). Such network-level insight has been achieved by advances in **voltage-sensitive dye imaging** of the whole ganglion. In principle, the entire local bend network can be monitored in parallel. This will lead not only to the identification of any unknown interneurons but also to a better understanding of information transfer (and loss) through population-coding networks.

Definition

LFPy is an open-source tool for calculating brain signals such as extracellular potentials and magnetic signals from simulated activity in multi-compartment neuron models, ranging from single cells to large neuronal networks. The tool is provided as a Python package and relies on the NEURON simulation environment.

Detailed Description

Electric extracellular measurements of neuronal activity in brain tissue have been one of the main workhorses in experimental neuroscience for several decades. Although such measurements are relatively easy to carry out, the large number of contributing sources to the measured signals renders the interpretation of the experimental data difficult. On the macroscopic scale, such as for measurements of the electric potential on the scalp, that is, electroencephalography (EEG) (Nunez and Srinivasan 2006), or measurements of magnetic fields outside the head itself, that is, magnetoencephalography (MEG) (Hämäläinen et al. 1993), the interpretation is further complicated by the fact that the measurements are performed some distance from the neural tissue itself. EEG signals are also affected by the different electric

conductivities of tissue between the brain and the electrodes (cerebral spinal fluid – CSF, bone and soft tissues) (Nunez and Srinivasan 2006).

The availability of biophysics-based *forward-modeling* tools is important for hypothesis testing with precisely defined mathematical models, where the experimental system, including neurons and measurement devices, is mimicked in the virtual model and simulated on a computer. Construction and improvements to *inverse* analysis methods applied to experimental data (i.e., inferring underlying neural activity from measurements) also call for improved forward-modeling tools. Inverse methods are required to better understand and analyze the link between measured brain signals and the underlying neural activity. Forward-modeling tools allow for models of measurements with known underlying neural activity, “ground truth”, that inverse methods can be validated against.

LFPy (LFPy.readthedocs.io) implements different established forward models for extracellularly recorded potentials and magnetic fields, stemming from activity in multicompartment neuron models (De Schutter and Van Geit 2009). Extracellular potentials in vicinity of the neurons are computed as distance-weighted sums of contributions from the transmembrane currents of the simulated neurons, while magnetic fields are either calculated from axial currents within the neurons or via the so-called current dipole moment calculated from the associated transmembrane currents. The current dipole moment is also used for EEG predictions. The corresponding electrostatic and magnetostatic forward models are derived using the appropriate volume conductor theory (Hämäläinen et al. 1993; Nunez and Srinivasan 2006; Einevoll et al. 2013).

Application

The first version of LFPy (Lindén et al. 2014, v1.0) incorporated the well-established scheme for extracellular potentials pioneered by Holt and Koch (1999), where transmembrane currents of multicompartment models are first computed using a domain-specific software (NEURON Simulation Environment, Carnevale and Hines (2006)). Then the extracellular potential is

computed as the distance-weighted sum over each current contribution, with weights derived using theory for an infinite homogeneous, isotropic, and ohmic volume conductor model.

This numerical scheme has been applied to predictions of the local field potential (LFP), that is, the low-frequency part of the extracellular potential (Pettersen et al. 2008; Lindén et al. 2010, 2011; Gratiy et al. 2011; Makarova et al. 2011; Schomburg et al. 2012; Łęski et al. 2013; Reimann et al. 2013; Martín-Vázquez et al. 2013, 2015; Głąbska et al. 2014; Mazzoni et al. 2015; Tomsett et al. 2015; Sinha and Narayanan 2015; Taxidis et al. 2015; Hagen et al. 2016, 2017; Głąbska et al. 2016; Ness et al. 2016, 2018; McColgan et al. 2017), as well as extracellular spike waveforms which carry more power at high frequencies (Holt and Koch 1999; Gold et al. 2006, 2007; Pettersen and Einevoll 2008; Pettersen et al. 2008; Franke et al. 2010; Schomburg et al. 2012; Thorbergsson et al. 2012; Reimann et al. 2013; Ness et al. 2015; Hagen et al. 2015; Miceli et al. 2017; Cserpán et al. 2017; Luo et al. 2018; Buccino et al. 2018, 2019).

Since LFPy 2.0 (Hagen et al. 2018), the tool has been extended to also support forward-model predictions accounting for anisotropic media, that is, with different conductivity in different directions (Goto et al. 2010), and discontinuous media where the conductivity is piecewise constant in a single direction. The latter can, for example, be used to mimic in vitro experimental setups using microelectrode arrays (MEAs) (Ness et al. 2015) or to mimic in vivo conditions where a jump in conductivity can be expected such as at the boundary between the brain and CSF. Furthermore, LFPy now incorporates calculations of axial currents across the neuronal morphology for estimating the magnetic field nearby the neuron (Blagoev et al. 2007). Hence, corresponding experiments using magnetic detection devices directly in neural tissue (Barbieri et al. 2016; Caruso et al. 2017) can be mimicked.

LFPy also features calculations of current dipole moments from transmembrane currents (Lindén et al. 2010), which is used for calculation of both EEG and MEG signals. For EEG predictions LFPy incorporates the analytical four-sphere

head model (Nunez and Srinivasan 2006), which was corrected by Næss et al. (2017), to account for the different conductivities of the brain, CSF, skull, and scalp. The computed current dipole moments can also be used with more complex head models (see, e.g., Huang et al. (2016)). MEG signal predictions in a spherically symmetric head model rely on a special form of the magnetostatic Biot-Savart law (ignoring effects of magnetic induction) (Nunez and Srinivasan 2006, Appendix C).

Finally, in contrast to its first release where the tool only supported simulations with a single cell instantiation at the time, LFPy also supports networks of synaptically interconnected neurons. Such network simulations can be executed on a single physical machine, but larger network simulations are better executed in parallel on high-performance computing (HPC) facilities (Hagen et al. 2018).

Architecture

LFPy is a Python package that presently (Hagen et al. 2018) provides different high-level class definitions which represent cells, populations, and networks of cells, synapses, intracellular stimulation devices (current and voltage clamps), and extracellular recording devices (representing both invasive and noninvasive equipment). LFPy's class definitions rely internally on NEURON's Python interface (Hines et al. 2009). As many illustrative LFPy usage examples are provided online (github.com/LFPy/LFPy/examples), we here only briefly summarize the main classes and their intended use and provide a simple use case below. The best way to learn the tool is by going through the various example files. More detailed technical documentation is available online (LFPy.readthedocs.io).

The most basic neuron representation in LFPy is provided by the `LFPy.Cell` class. A `Cell` object is typically instantiated with a chosen morphology, either on the form of a morphology file with instructions NEURON can digest (with file endings “.hoc,” “.asc,” “.swc,” or “.xml”) or a NEURON `SectionList` instance filled with `Section` references. A number of optional arguments can be used to set the passive parameters of

the cell model; additional routines to distribute, for example, active ion channels to different parts of the neuron; rules for spatial discretization of the corresponding cable model; and simulation settings (temporal duration and discretization). After instantiation, the cell object has several public methods that can be used to position and align the cell in space, return indices of different compartments of the model, and run the simulation.

Two additional classes are defined using inheritance from class `Cell`, namely, `TemplateCell` and `NetworkCell`. These can be used with existing “network-ready” single-cell models that use NEURON's *template* definitions which allow for multiple concurrent instantiations of individual neurons. In LFPy, however, the `TemplateCell`'s intended use is still for handling single-neuron simulations (serially), while `NetworkCell` objects are instantiated in neuronal network populations.

After a cell's instantiation, it can be instrumented with synapses by the creation of an arbitrary number of instances of class `LFPy.Synapse`. The main parameters of the `Synapse` class are a reference to the cell object itself, the compartment index where the synapse is located, and synapse type with synapse-specific parameters (time constants, weight, reversal potential, etc.). The synapse current and postsynaptic potential can optionally be recorded during the course of a simulation. The instantiated synapse has public methods to set its activation times, to either explicit values or determined stochastically using NEURON's `NetStim` class.

Intracellular stimulation devices (current and voltage clamps) can be set up using LFPy's `StimIntElectrode` class. The class is instantiated similar to synapses, but the name of point-process type has to be defined as well as its specific parameters. Recording of stimulation current and corresponding compartment membrane voltage can optionally be enabled.

The creation of networks, or simply different populations of concurrent `NetworkCell` instantiations, is in LFPy incorporated through its `Network` class. Its main parameters are the temporal discretization and duration of the simulation, the globally shared initial voltage for

compartments and simulation temperature which affects the active ion-channel dynamics. The network instance contains a public method to create populations of the same cell type (through class `Population`), that is, with the same parameters being passed to the `NetworkCell` instances upon their creation. The network also contains a public method to connect pre- and postsynaptic populations using shared synaptic parameters. Values for connection weights, delays, and synaptic locations can however be drawn randomly from desired function declarations such as `np.random.normal` with corresponding parameters or be set to constant values.

Example Code

Here, we demonstrate how to set up a simple LFPy simulation in Python. We define a simplified neuron representation with an active soma compartment and passive apical dendrite which receives strong synaptic input at the terminating end of the dendrite, with simultaneous calculation of the extracellular potential alongside the neuron. We first create a “ball and stick” morphology file, with a passive dendrite and active soma using NEURON’s HOC syntax from Python:

```
morphology = 'BallAndStick.hoc'
with open(morphology, 'w') as f:
    f.writelines(""" Create sections:
create soma[1]
create apic[1]
// Add 3D information:
soma[0] {
    pt3dadd(0, 0, -15, 30) // x,y,z,d in
um
    pt3dadd(0, 0, 15, 30)
}
apic[0] {
    pt3dadd(0, 0, 15, 3)
    pt3dadd(0, 0, 1015, 3)
}
// Connect section end points:
connect apic[0](0), soma[0](1)
// Set biophysical parameters:
forall {
    Ra = 100. // ohm*cm
    cm = 1. // uF/cm2
}
soma { insert hh }
apic {
```

```
insert pas
g_pas = 0.0002 // S/cm2
e_pas = -65. // mV
}""")
```

We then proceed to set up the simulation of the model, by first importing different classes from LFPy and also other packages we may need:

```
from LFPy import Cell, Synapse,
RecExtElectrode
import numpy as np
import matplotlib.pyplot as plt
```

First we instantiate the cell model, providing the name of the morphology file as well as simulation duration and resolution, and initial voltage for all compartments:

```
cell = Cell(morphology=morphology,
            tstop=100., # ms
            dt=0.05, # ms
            v_init=-65. # mV
            )
```

Next we instantiate the synapse with compartment index information, parameters for the chosen synapse mechanism, and set synaptic activation times:

```
synapse = Synapse(cell=cell,
                  idx=cell.get_idx(section='apic')
                  [-1],
                  syntype='ExpSyn',
                  weight=0.05, # uS
                  tau=5., # ms
                  e=0., # mV
                  record_current=True)
synapse.set_spike_times(np.array([10.,
15., 20., 25., 60.])) # ms
```

Then we instantiate the extracellular recording device, with a chosen value for the homogeneous extracellular conductivity and locations for the electrode contact points in space:

```
z = np.linspace(-100, 1100, 25) # um
electrode = RecExtElectrode
(sigma=0.3, # S/m
 x=np.zeros(z.size)+10,
 y=np.zeros(z.size),
 z=z)
```

Finally, we can simulate the model and predict the resulting extracellular potential:

```
cell.simulate(electrode=electrode)
```

The “simulate” method of the cell does not return any data for storing, visualization, etc. but sets various attributes of the instantiated class objects. For the present example, these are “cell.tvec,” “cell.somav,” “synapse.i,” and “electrode.LFP”. These are all numpy array types which can easily be plotted using matplotlib, for example (see model output in Fig. 1). The membrane depolarizations caused by the synapse current (I_{syn}) result in action potentials at the soma (V_{soma}). Both synaptic input and action potentials result in traveling features in the extracellular potential (image plot), toward the soma for synaptic input and from the soma for action potentials. These

features are governed by the passive dendritic cable properties.

Electrostatic Forward Models

As the different electrostatic and magnetostatic forward models in LFPy are described in detail in Hagen et al. (2018), we here briefly summarize their main assumptions.

The relation between extracellular potentials and transmembrane currents is governed by volume conductor theory (Nunez and Srinivasan 2006; Einevoll et al. 2013). At frequencies relevant for neuronal processes (below 10,000 hertz or so), the derivation of the volume conductor theory from first principles is simplified by application of the so-called quasistatic approximation to Maxwell’s equations (Hämäläinen et al. 1993, p. 426). The extracellular medium is in all cases assumed to be *ohmic*, which implies a linear and

LFPy: Multimodal Modeling of Extracellular Neuronal Recordings in Python, Fig. 1 Single-cell example output. The morphology, synapse site (red dot), and recording locations (black dots) are shown on the left. The

respective synapse current (I_{syn}), soma potential (V_{soma}), and extracellular potential (ϕ) are shown as function of time from top to bottom

frequency-independent relation between currents and electric potentials (Pettersen et al. 2012; Einevoll et al. 2013; Miceli et al. 2017). Then, the simplest possible case is that of an *infinite homogeneous* (same in all locations) and *isotropic* (same in all directions) volume conductor (see, e.g., Hagen et al. (2018, Section 2.2.1)). The medium can then be simply represented by a *scalar* extracellular conductivity, which assumes that local variations throughout the tissue from glia, dendrites, axons, cell bodies, etc. are negligible when estimating the extracellular potential. This assumption of homogeneity appears valid for simulations mimicking recordings in, for instance, cortical gray matter (Goto et al. 2010).

For simple, analytically tractable circumstances, LFPy may also account for both inhomogeneous and anisotropic extracellular media. Inhomogeneities on the macroscopic level may arise at the interface between different tissue types such as white and gray matter or between the gray matter and the conductive CSF on top of cortex. For such cases, LFPy can account for the effects of a discontinuous jump in conductivity by use of the so-called method of images (MoI); see Hagen et al. (2018, Section 2.2.2) for details. Another application of the MoI has been to mimic in vitro experimental setups, where jumps in conductivity occur between the petri dish, the tissue sample, and the saline layer covering the sample (Ness et al. 2015).

LFPy also supports forward-model predictions with homogeneous *and* anisotropic media, meaning that the electric conductivity may depend on direction but not location. This functionality may be utilized to mimic anisotropy in cortex (Goto et al. 2010), assuming that the typical orientation of dendritic and axonal fibers may affect the conductivity. For details on the implementation, see Hagen et al. (2018, Section 2.2.3).

In order to predict EEG signals, LFPy provides the analytically tractable four-sphere head model (Nunez and Srinivasan 2006; Næss et al. 2017). This simplified head representation assumes radial symmetry, and the different electric conductivities of the brain, CSF, skull, and scalp are accounted for by corresponding concentric shells

with homogeneous and isotropic conductivity. Neuronal sources assumed to be some distance away from the measurement site are represented by their *current dipole moment*, computed from the transmembrane currents in the neurons; see Hagen et al. (2018, Section 2.3.1).

The very same current dipole moment is utilized in order to compute distal MEG signals, computed using a special form of the corresponding magnetostatic Biot-Savart law (Nunez and Srinivasan (2006, Appendix C); Hagen et al. (2018, Eq. 16 in Section 2.3.5)). When computing magnetic fields in proximity to the neurons, the axial currents computed from the membrane voltage in each compartment are used instead of the current dipole moment. In both cases, negligible contributions from volume currents to magnetic signals are assumed, that is, axial currents within neurons are the main contributors to magnetic measures of brain activity (Hämäläinen et al. 1993).

Extensions to LFPy

As LFPy is written in Python, a transparent and easy-to-learn programming language, LFPy's areas of application may with relative ease be extended to other measurement modalities or different forward models. Geometrically complicated variations in extracellular conductivity (including those introduced by the electrode device) can be accounted for using finite-element modeling (FEM (Logg et al. 2012; Lempka and McIntyre 2013; Ness et al. 2015; Næss et al. 2017; Buccino et al. 2019)) in order to map transmembrane currents to extracellular signals. In a similar manner, current dipole moments computed using LFPy can be used with detailed head models constructed from MRI data (Bangera et al. 2010; DeMunck et al. 2012; Vorwerk et al. 2014; Huang et al. 2016). Frequency-dependent conductive media may be accounted for by treating each Fourier component of recorded signals independently as pursued in Miceli et al. (2017).

One specific extension of the forward modeling scheme in LFPy is the so-called hybrid scheme for LFP predictions from point-neuron networks (Hagen et al. 2016). There, the

simulation of ongoing spiking activity is first conducted offline using simplified neuron representations. The resulting spikes are used as activation times of synapses distributed onto geometrically detailed multicompartment neuron models, before each individual cell's contribution to the LFP is simulated independently before summing up all contributions. Thus, the prediction of extracellular signals (LFP, EEG, MEG, etc.) of large neuronal networks is simplified by its disentanglement from simulations of recurrent network activity. Furthermore, the arduous effort of fine-tuning parameters of recurrently connected networks of biophysically detailed neuron models is avoided.

Another extension to LFPy is detailed models of extracellular electric stimulation of neurons. LFPy do not include forward models for the effect of electrode stimulation currents onto neurons per se but such can easily be constructed using the same assumptions as discussed above. These models will in fact be closely related to forward models mapping transmembrane current contributions to measured electrode potentials (through reciprocity). Given a prediction of the extracellular potential across the neuron's outer surface, it can already be set as a cable equation boundary condition using the `Cell.insert_v_ext` method, which relies internally on NEURON's extracellular mechanism.

Deployability and Documentation

LFPy is freely available (General Public License v3), runs on most common desktop computer operating systems (Linux, Unix, macOS, and Windows), and is presently tested with multiple versions of Python (2.7, 3.4–3.7). The software is made to run on computers ranging from laptops to HPC facilities. Its main dependencies upon installation are NEURON (neuron.yale.edu) installed with bindings to Python (Hines et al. 2009), NumPy (numpy.org), SciPy (scipy.org), h5py (h5py.org), mpi4py (bitbucket.org/mpi4py/mpi4py), and Cython (cython.org).

Installation

NEURON can usually be installed using pre-compiled installers directly from its homepage

(neuron.yale.edu), but certain systems (e.g., non-standard operating system configurations and HPC systems) may require compilation from source. More detailed instructions for installing both LFPy and NEURON on different common operating systems are provided through LFPy's online documentation (lfp.readthedocs.io).

The easiest way of installing stable releases of LFPy and its dependencies (except NEURON) is from the Python Package Index using the `pip` utility, by issuing in the terminal:

```
pip install LFPy --user
```

An existing installation can be upgraded by issuing:

```
pip install --upgrade --no-deps LFPy
--user
```

Here, the `--no-deps` option disables attempts to update also other installed dependencies. The software can be removed by issuing:

```
pip uninstall LFPy
```

Alternatively, LFPy can be installed from source code hosted at [GitHub.com/LFPy/LFPy](https://github.com/LFPy/LFPy). This repository contains the entire development history of LFPy using Git (<https://git-scm.com>). Installation of LFPy from source can be executed as follows:

```
cd <where to put LFPy sources>
git clone https://github.com/LFPy/LFPy.git
cd LFPy
pip install requirements.txt --user
python setup.py install --user
```

The GitHub homepage also offers the option to directly download compressed (zip or tar.gz) files with the source codes of LFPy.

In addition to the above requirements, also matplotlib (matplotlib.org) and the Jupyter Notebook (jupyter.org) are required to run all the example simulation scripts provided with LFPy. The different example files are provided with the LFPy source codes in the folder named `examples`.

Development and Documentation

Active development and bug/issue tracking related to LFPy are conducted in public at [GitHub.com/LFPy/LFPy](https://github.com/LFPy/LFPy). Fixes and new features are usually handled through Pull Requests, with automated build testing using Travis CI (travis-ci.org/LFPy/LFPy) and test coverage testing using Coveralls (coveralls.io/github/LFPy/LFPy). The full documentation for LFPy is provided at Read the Docs (lfp.readthedocs.io).

Definition

Local field potentials (LFPs) are biosignals representing the activity of large neuronal populations that can be recorded from intracranial low-impedance electrodes. Electrodes implanted in the human basal ganglia and other subcortical

structures for deep brain stimulation (DBS) therapy in patients with movement and neuropsychiatric disorders can be used to record deep LFPs. The analysis of LFPs in patients after DBS surgery, particularly those with Parkinson's disease, revealed that the basal ganglia information encoding is based on oscillations that respond to movements, behavioral stimuli, cognitive processing, and emotional arousal. The LFP oscillatory code in the last decade helped in clarifying basal ganglia pathophysiology and was regarded as possibly implicated in the still unknown DBS mechanisms of action.

LFPs were hence studied during and after DBS, to understand whether changes in the oscillatory code may reflect the DBS clinical effect of patient's symptoms.

In patients with Parkinson's disease, even though the exact mechanisms remain controversial, ample evidence shows that DBS specifically modulates LFP oscillations. Also in dystonia, pallidal DBS affects some specific oscillations that could be connected with hyperkinesias. The DBS action on LFPs depends on the stimulation voltage, and LFP-specific oscillations can be used to finely tune DBS stimulation frequency.

LFP analysis during DBS, despite providing fundamental insights on basal ganglia pathophysiology in movement disorders, has contributed to a significant advancement on the technology for DBS, being the basis of new adaptive DBS (aDBS) systems that are able to change moment-by-moment DBS stimulation parameters (frequency, voltage, pulse width, etc.) according to the patient's clinical state as reflected by the oscillatory LFP code.

Detailed Description

DBS and Deep Electrophysiological Recordings in Humans

Deep brain stimulation (DBS) is remarkably effective in treating movement disorders such as Parkinson's disease (PD), dystonia, and essential tremor (Benazzouz et al. 1993; Pollak et al. 1993; Moro et al. 1999, 2010; Volkmann 2004; Vidailhet et al. 2005; Nazzaro et al. 2012;

Pizzolato and Mandat 2012). DBS surgery includes a first surgical procedure for stereotactic electrode implantation into specific nuclei of the basal ganglia or other subcortical structures. After that, a secondary surgery is performed to insert the electrical pulse generator in a submuscular pouch under the pectoralis major muscle and to connect it to the electrodes previously positioned.

The location of DBS electrodes depends on the type of neurological disorders and the predominant symptoms of patient. The subthalamic nucleus (STN) is the election target for PD, even though the globus pallidus internus (GPi) is sometimes used to control symptoms (Anderson et al. 2005), as well as the thalamic ventralis intermedius (VIM) (Woods et al. 2001) and pedunculopontine nucleus (PPN) (Tykocki et al. 2012). The GPi is presently the election target for dystonia (Vidailhet et al. 2005), whereas patients with essential tremor are mainly implanted in VIM (Nazzaro et al. 2012). In the past years, encouraging data obtained in patients with severe depression, obsessive-compulsive disorders, and Gilles de la Tourette syndrome have extended DBS therapeutic applications to neuropsychiatric disorders (Mallet et al. 2008; Aouizerate et al. 2009; Porta et al. 2009; Greenberg et al. 2010; Ward et al. 2010; Goodman and Alterman 2012). In these pathologies, the election target structure is still under research and widened the panorama of the structures in which DBS electrodes are implanted, including the nucleus accumbens (Priori et al. 2013) and the hypothalamus (Rosa et al. 2012a).

Although ample evidence, obtained over the past decade, shows that DBS reduces motor disability and improves quality of life of patients with movement disorders, the mechanism underlying the therapeutic action of DBS remains essentially unexplained (Rosa et al. 2012b).

Despite enormous progress achieved by experimental studies and functional models (Wichmann and DeLong 1996), little is known about the signals controlling information processing and integration in the human basal ganglia, “the dark basement of the brain” (Wilson 1925). From a scientific viewpoint, DBS provides a unique window into the human basal ganglia, thus helping to understand the neurophysiological mechanisms

underlying motor functions and cognitive and behavioral information processing. In fact, DBS electrodes offer a unique opportunity to record the electrical activity from the basal ganglia and the other subcortical structures in which electrodes are implanted.

There are two main time windows in which electrodes allow to record electrical activity in the target deep brain structures. During DBS surgery, high-impedance exploratory microelectrodes are used to record the activity of single neurons to optimize the DBS target localization before the final electrodes are definitively implanted. Besides serving clinical purposes, single-unit (SU) recordings also provide a powerful research tool, to correlate anatomical, functional, and electrophysiological information (Levy et al. 2000, 2001; Stefani et al. 2002; Romanelli et al. 2004). After the final DBS electrodes implant and before its leads are connected to the subcutaneous electrical pulse generator, electrodes are accessible for electrophysiological recordings from the target structure. Because the final DBS electrodes have low impedance, they are unsuitable for recording single-neuron activity but are ideal for recording local field potentials (LFPs).

What Are LFPs?

LFPs reflect the synchronous presynaptic and postsynaptic activity in large neuronal populations and can detect focal network rhythms that are not necessarily observable in single neurons or neuron pairs (Levy et al. 2002; Priori et al. 2004; Brown and Williams 2005; Kuhn et al. 2005b; Zaidel et al. 2010; Marceglia et al. 2011).

LFP recordings and analysis demonstrated for the first time the oscillatory nature of basal ganglia (Brown 2003). This was in line with several studies showing that basal ganglia functional processes are mediated not only by firing rates but also and mainly by firing patterns (Bevan et al. 2002; Terman et al. 2002), oscillatory phenomena (Gatev et al. 2006; Uhlhaas and Singer 2006; Wilke et al. 2006), and wave propagation (Rubino et al. 2006).

LFP recordings provide more information than SU recordings, not only because LFPs can detect focal network rhythms but also because, unlike SU, LFPs can be recorded both intraoperatively (Weinberger et al. 2006; Bronte-Stewart et al. 2009) and days after DBS surgery. Researchers can study LFPs at different intervals from DBS electrode implant: acute phase (3–4 days after surgery) (Foffani and Priori 2006; Priori et al. 2006), chronic phase (30 days after surgery) (Rosa et al. 2011), and hyperchronic phase (years after surgery) (Giannicola et al. 2012). Moreover, patients are typically free to move during LFP experimental recordings, and they can be engaged into more complex and ecological tasks than during DBS surgery while SUs are recorded.

The Oscillatory LFP Code

A huge amount of LFP studies in humans revealed in the last 15 years unknown functions of basal ganglia particularly in PD patients during the execution of motor, cognitive, and behavioral tasks showing the existence of a “code” in LFP oscillations corresponding to the clinical condition of patient (Table 1) (Marceglia et al. 2007).

Basal ganglia LFPs oscillate in several frequency bands, ranging from low frequencies (2–7 Hz), to beta frequencies (8–20 Hz, alpha/low beta; 21–35 Hz, high beta), gamma frequencies (60–80 Hz), and very high frequencies (250–350 Hz).

The most studied and debated STN LFP oscillations are in the beta range because they seem to reflect the patient’s motor state. Beta band LFP activity, especially in the lower frequency range (8–20 Hz), and its nonlinear interactions are disrupted by antiparkinsonian medication (Levy et al. 2002; Foffani et al. 2003; Priori et al. 2004; Marceglia et al. 2006; Weinberger et al. 2006; Giannicola et al. 2010, 2013) and correlate with motor symptoms (Kuhn et al. 2004, 2006b, 2008; Ray et al. 2008; Zaidel et al. 2010). Otherwise, STN low frequencies [alpha (4–10 Hz)] correlate with dyskinesias: when the patient experiences dyskinesias, the low-frequency rhythm, particularly around the 8 Hz range, dramatically

increases (Foffani et al. 2005a; Alonso-Frech et al. 2006; Rodriguez-Oroz et al. 2011). Very low-frequency LFPs increase after anti-parkinsonian medication, thus confirming that they correlate with an improvement in the patient’s clinical condition (Priori et al. 2004), even though their overboosting is associated with hyperkinesias (Silberstein et al. 2003; Obeso et al. 2004; Priori et al. 2004). As well as inducing changes in low frequencies, increasing dopaminergic medications also modulates gamma and very high frequencies (Foffani et al. 2003; Brown and Williams 2005; Lopez-Azcarate et al. 2010). Very high-frequency LFP changes may be involved in the mechanism responsible for the therapeutic actions of DBS (Foffani and Priori 2006) on motor symptoms.

Basal ganglia LFP oscillations are also involved in motor execution. STN and PPN LFP beta oscillations correlate with all phases of voluntary movement: preparation, execution, and recovery (Foffani et al. 2005b; Tsang et al. 2010), whereas alpha oscillations in the PPN correlate with gait performance (Thevathasan et al. 2012).

Specific LFP oscillations in the STN might intervene in non-motor processing (Marceglia et al. 2011). In particular beta LFP oscillations correlate with motor representation including action organization and context recognition (Kuhn et al. 2006a; Marceglia et al. 2009) and with response inhibition (Rektor et al. 2009; Ray et al. 2011; Anzak et al. 2012; Alegre et al. 2013); low-frequency LFP oscillations correlate with cognitive information related to decision making (Cavanagh et al. 2011; Fumagalli et al. 2011; Rosa et al. 2013) and alpha/low beta with limbic and emotional information (Kuhn et al. 2005a; Brucke et al. 2007; Huebl et al. 2011; Buot et al. 2013). These observations suggest that LFP oscillations are also markers reflecting changes in patients’ cognitive and behavioral state and that controlling them might prevent post-DBS cognitive and behavioral impairments (Marceglia et al. 2011).

The presence of multiple rhythms at different frequencies differentially modulated by movement and drugs consistently supported the hypothesis that pathological oscillations recorded

Local Field Potential and Deep Brain Stimulation (DBS), Table 1 Local field potential code in movement disorders

through LFP activity are involved in the physiology of movement disorders and are crucial for understanding the mechanisms of DBS action.

DBS Action on the Oscillatory LFP Code

Mechanisms underlying the remarkable DBS efficacy in reducing motor and non-motor symptoms related to movement disorders remain largely unclear. The study of the interaction between LFPs and DBS was regarded as able to provide insight into this debate. At present, the main results, given the wider number of patients undergoing DBS surgery in the last decade, were obtained for PD, recording LFPs from STN. Only one study recorded LFPs from GPi in patients with dystonia (Table 2).

STN LFPs and DBS in PD

Despite the large spectrum of oscillations characterizing STN LFPs, the beta band (8–30 Hz) and the low-frequency band (2–7 Hz) were mainly investigated provided their consistent and specific response to antiparkinsonian medication and movement (Table 1). Aiming to understand whether DBS may mimic the drug effect and mechanism of action, studies focused on LFP response to DBS first addressed beta and low-frequency modulations. Even though the exact mechanisms remain controversial, ample evidence shows that DBS specifically modulates LFP oscillations in patients with PD.

The main issue to be faced while studying LFP response to DBS is the huge artifact produced by the stimulation pulse (Rossi et al. 2007). The stimulus artifact saturates the recording preamplifier and prevents from LFP recording while DBS is on.

For this reason, as a first step, researchers investigated LFP response immediately after DBS was turned off (Brown et al. 2004; Foffani et al. 2006; Priori et al. 2006; Wingeier et al. 2006; Kuhn et al. 2008; Bronte-Stewart et al. 2009), obtaining controversial results. Whereas some works reported an STN DBS-dependent decrease of beta oscillations in both STN and GPi nucleus (Brown et al. 2004; Wingeier et al. 2006; Kuhn

et al. 2008; Bronte-Stewart et al. 2009), others failed to confirm this result (Foffani et al. 2006). Moreover, the same authors, instead of observing a DBS-dependent beta decrease, reported a consistent increase in the very low-frequency activity that could be observed in all the patients studied and that correlated with the clinical response to DBS ceasing (Priori et al. 2006).

However, this experimental approach had several drawbacks: (i) even though the implanted electrodes were already connected to the recording system when DBS was turned off to start LFP recordings, the amplifier saturation stopped after some seconds, thus preventing from the investigation of the DBS on–off transition; (ii) some rhythms responded to the DBS stimulus almost immediately, and responses were difficult to detect after DBS was turned off because the transition could not be recorded; and (iii) this approach did not guarantee, a priori, that LFP changes observed after turning DBS off reflect LFP changes taking place during DBS.

To overcome such barriers, Rossi et al. (2007) proposed a new technology, called FilterDBS, able to record LFPs while DBS was turned on from the same electrode. FilterDBS is based on a two-stage amplification in which, after a low pre-amplification stage, a low-pass filter is applied to the recording signal cutting the frequency components above 50 Hz, before a second amplification stage. This technology prevented from DBS-dependent amplifier saturation, working on the frequency separation between the LFP oscillatory components and DBS stimulation frequency. The introduction of FilterDBS demonstrated that LFPs can be recorded without turning DBS off, that LFP signals can be continuously recorded and analyzed during DBS therapy, and that LFPs are modulated during DBS, thus opening the window on DBS-induced changes in STN LFP oscillations.

The first studies with LFPs recorded during DBS confirmed some previous results: whereas DBS-induced beta decrease was not observable in all patients, a low-frequency increase of controversial nature was consistently present in all patients (Rossi et al. 2008) (Fig. 1a).

Upward arrows indicate an increase; downward arrows indicate a decrease. The symbol $\approx$ means no change. *GPi* globus pallidus internus, *GPe* globus pallidus external, *PD* Parkinson's disease

^aOnly patients that demonstrated a temporary persistence of clinical benefit after cessation of DBS were analyzed

^bOnly in nuclei with significant beta band activity at baseline

^cIn selected patients with a discrete spectral peak in the beta band

^dOnly in patient with DYT3+ dystonia

After that, studies combining pharmacological (levodopa) and electrical (DBS) therapy showed that whereas levodopa produced a specific disruption of the beta oscillation in all patients, DBS-induced decrease in the beta band was limited to those patients having a high beta activity at rest. In addition, in the combined levodopa–DBS therapy administration, which is a common situation in the clinical chronic DBS setting, the levodopa-induced effect predominates (Giannicola et al. 2010) (Fig. 1b).

Conversely, another study using a similar methodology showed that DBS suppressed global beta oscillations in all nuclei selected (Eusebio et al. 2011) (Fig. 1c). Even though this finding seems to contradict the results of Giannicola et al. (2010), it is important to underline that Eusebio and colleagues selected only nuclei that showed significant high beta peak, thus indirectly confirming Giannicola's results. During DBS, a stimulation-dependent low-frequency increase starts when DBS is turned ON and is consistent across patients (Giannicola et al. 2013). This observation agrees with the STN DBS-induced low-frequency band increase observed minutes after DBS is turned off and also corresponds with the persistent STN DBS-induced improvement in the patients' clinical state (Priori et al. 2006; Rossi et al. 2008).

Evidence on the correlation between patient's clinical state and DBS-induced changes in LFPs suffers nevertheless from a major drawback, namely, that all experimental sessions took place within days after brain surgery when a lesion effect and local brain edema remain. To date, only two studies have investigated how DBS influences LFPs recorded more than 1 week after DBS surgery (Rosa et al. 2011; Giannicola et al. 2012). Rosa et al. (2011) investigated STN LFPs recorded in PD patients 30 days after surgery for DBS electrode placement and compared them with those recorded immediately after surgery. To do so, the surgery for electrical pulse generator implant, which usually takes place some days after the surgery for DBS electrode placement, was postponed, ensuring patient's safety, without any adjunctive complication. Thanks to this protocol, it was possible to show that weeks after

DBS electrode implant, STN LFPs remain stable and that in a subgroup of patients whose recordings showed a strong beta activity at baseline, LFP beta activity recorded during DBS decreased immediately after and 30 days after DBS surgery (Rosa et al. 2011) (Fig. 1d). Moreover, studying LFPs during battery replacement surgery, Giannicola et al. (2012) showed that rest LFP oscillations recorded before DBS were turned on and before levodopa administration a few days after DBS electrode implant remain almost unchanged after patients receive chronic DBS for 7 years. The effect of DBS on LFPs does not change years after DBS electrode implantation and chronic stimulation: whereas in a subgroup of patients, whose LFP recordings showed strong beta activity at baseline, beta activity decreased, and low-frequency activity invariably increased.

Pallidum LFPs and DBS in Dystonia

Only one study investigated LFP activity in the globus pallidus during high-frequency DBS in patients with dystonia (Whitmer et al. 2013). Whitmer et al. recorded LFP from GPi and GPe in a patient with DYT3+ dystonia at rest and during high-frequency DBS showing that alpha (4–10 Hz) and beta (13–35 Hz) bands had visible peak at rest and were attenuated during DBS in both nuclei with immediate and dramatic improvement of patient's symptoms. In the same study alpha and beta bands were not attenuated during DBS in the patient with secondary dystonia, and 6-month follow-up did not show measurable benefit from DBS. Authors speculated that the reduction of LFP activity in specific bands during pallidal DBS would result in an improvement in dystonic symptoms. In particular results showed by Whitmer et al. raise the question whether beta activity now recorded in both primary (Silberstein et al. 2003; Weinberger et al. 2006; Liu et al. 2008) and secondary dystonias may play a pathophysiological role in hyperkinesias.

What Happens if We Change Stimulation Voltage?

Eusebio and colleagues recorded LFPs during continuous increase of voltage of high-frequency

Local Field Potential and Deep Brain Stimulation (DBS), Fig. 1 (continued)

stimulation and showed significant attenuation of the power of beta band during high-frequency DBS at clinically therapeutic voltage levels (≥ 2 V), but not at voltages below 1.5 V (Eusebio et al. 2011) (Fig. 1c).

In a different study, Whitmer et al. tested whether the STN LFPs were attenuated during DBS and, if so, whether the degree of attenuation increased with higher DBS voltages, comparing DBS in two regions of STN: dorsal to and within the STN. The results demonstrated that the beta band was attenuated during high-frequency DBS; the degree of attenuation monotonically increased with DBS voltage in both locations, but this voltage-dependent effect was greater in the central STN than the dorsal STN. In particular DBS dorsal to STN attenuated beta power only at 3 V, whereas DBS within STN attenuated relative beta at voltage >1.5 V (Whitmer et al. 2012). The question as to whether beta and its DBS-induced attenuation correspond to the location of maximally clinically efficacious stimulation remains to be determined.

What Happens if We Change Stimulation Frequency?

In PD, LFP activity in the gamma/high gamma and high frequency range is considered as

fundamental to promote movements and force with specific patterns of the gamma activity observed when patients move (Foffani et al. 2003; Brown and Williams 2005; Anzak et al. 2012; Tan et al. 2012; Alegre et al. 2013). These observations in PD were confirmed by those in dystonia (Brucke et al. 2012). Conversely, the beta activity is considered as “antikinetic,” at least when the beta oscillation is concentrated in its low range.

On this basis, one study addressed the problem of changing DBS stimulation frequency. The authors, after studying the LFP pattern of patients during the levodopa on condition and during movements, compared standard DBS, no DBS, and DBS administered at the low frequency (4–10 Hz), beta frequency (11–30 Hz), and gamma frequency (31–100 Hz). Individual frequencies were obtained measuring the highest decrease in the low-frequency and in the beta band, and the greatest increase in the gamma frequencies when the patient was on medication and during movements. The authors showed that, whereas low-frequency and beta DBS worsen the motor Unified Parkinson’s Disease Rating Scale (UPDRS) scores, the gamma frequency DBS improved it. However, the UPDRS improvement obtained during gamma stimulation did not differ

Local Field Potential and Deep Brain Stimulation (DBS), Fig. 1 Subthalamic local field potentials and deep brain stimulation. (a) Subthalamic local field potential (STN LFP) power spectrum changes during DBS in patients with Parkinson’s disease (PD) (grand average, 16 nuclei). Top: time course of LFP power spectrum changes over 12 min (deep brain stimulation [DBS] for 8 min). DBS begins at the vertical black dashed line on the left and ends at the vertical black dashed line on the right. Bottom: instantaneous power spectra before DBS (baseline) on the left and 4 min after DBS began, on the right. Black lines: the average spectrum; gray lines spectra of individual nuclei. Note that during STN DBS the low-frequency power increases and beta power remains unchanged. (b) Time course of STN LFP in a representative patient with PD. STN LFP time-varying power spectrum in the beta band (8–20 Hz). Top: time–frequency plot over the entire experimental session (50 min total time, 42 min DBS); the black dotted lines, from the left, correspond to turning DBS on, to the clinical effect of levodopa, and to turning DBS off. Bottom: transient states when DBS was turned on (left panel) and off (right panel). Note that

levodopa and DBS both reduced beta oscillations but that the levodopa-induced effect predominates. (c) Effect of DBS on STN LFP in a representative patient with PD. On the right power autospectrum of LFP recorded without stimulation. On the left time–frequency log power LFP spectrum. Bars along the time axis denote ongoing DBS at 2.0 and 3.0 V. Note that DBS at ≥ 2.0 V suppressed the spectral peak, stimulation at 1.5 V transiently increased power peak, and stimulation at 3.0 V delayed its return after stimulation ended. (d) STN LFPs recorded immediately (t-0h) and 30 days (t-30d) after DBS surgery in patients with PD: grand average for nuclei showing significant beta band ($n = 6$ nuclei) power spectral density (PSD) in the three experimental conditions: prestimulation (baseline – black, solid line), during stimulation (DBS on – gray, dashed line), and after stimulation (DBS off – light gray, dashed line). Beta band PSD was aligned on beta peak of each nucleus (0 Hz). Note that beta band power decreases in the on DBS condition in both t-0h and t-30d for nuclei with significant beta band power (Reproduced from Rosa et al. (2012b) with permission from Elsevier)

from that obtained during standard high-frequency stimulation, and UPDRS worsening with low-frequency and beta DBS did not differ from the no DBS condition (Tsang et al. 2012). These results seem in contrast with other studies showing that STN DBS in the gamma range (around 50–60 Hz) did not provide PD motor signs reduction (Rizzone et al. 2001; Moro et al. 2002). However, in these past studies, gamma frequencies were not chosen according to the patient-specific LFP pattern, thus suggesting that DBS specifically interferes with the oscillatory code of the patient in the high frequency range (Foffani and Priori 2006).

LFPs and DBS Mechanisms of Action

The prevalent hypothesis that beta band is a pathological marker of PD motor signs is supported by correlations between improved motor impairments and attenuated beta after medication (Foffani and Priori 2006; Kuhn et al. 2006b, 2008; Weinberger et al. 2006; Ray et al. 2008). The attenuation of beta during high-frequency DBS would lend further evidence in support of this hypothesis because DBS also alleviated PD motor symptoms (Deuschl et al. 2006; Kuhn et al. 2008; Ray et al. 2008) raising the possibility that suppression of pathological activity may mediate the effects of DBS.

Evidence that DBS acts by modulating pathological oscillatory activity towards a pattern that the basal ganglia–cortical system finds more physiological receives strong support from several studies (Silberstein et al. 2005; Kuhn et al. 2006b; Giannicola et al. 2012). STN DBS acts not only by modulating pathological STN activity but also by projecting modulated activity to GPi and SNr (Hammond et al. 2007), the output structures in the basal ganglia. The new STN DBS-driven output might be more palatable to basal ganglia–cortical loops supporting the hypothesis that effective therapies (both medication and DBS) shift overall activity patterns towards a more regular pattern that is better tolerated by the system and manifested by clinical improvement (Kopell et al. 2006).

In particular, in PD, the pathological activity could be the excessive beta synchronization and the efficacy of STN DBS could depend on the regularization of STN activity and suppression of synchronized activity observed in downstream nuclei. Moreover, the stimulation amplitude and frequency dependency of DBS efficacy could stem from whether stimulation is able to effectively suppress and or regularize the pathological oscillations observed in basal ganglia (Cagnan et al. 2009; Hahn and McIntyre 2010).

LFPs for the Future of DBS Therapy: Adaptive DBS Systems

LFP analysis during DBS, despite providing fundamental insights on basal ganglia pathophysiology in movement disorders, has contributed to a significant advancement on the technology for DBS, being the basis of new adaptive DBS (aDBS) systems (Priori et al. 2013).

In fact, present technology provides DBS with constant stimulation settings that are adjusted only during control visits. This stimulation strategy is in contrast with the nature of the pathologies treated with DBS that typically fluctuate over time and, therefore, leaves symptoms partly uncontrolled (Krack et al. 2003; Deuschl et al. 2006; Romito and Albanese 2011). A system able to adapt moment-by-moment stimulation parameters to the patient's clinical condition would hence overcome such limitations. In addition, increasing evidence suggests that several cognitive and behavioral adverse effects, observed years after DBS therapy started, are related to the amount of stimulation delivered (Bronstein et al. 2011; Romito and Albanese 2011).

To obtain a “fine-tuning” of DBS settings (including frequency, amplitude, pulse width, and waveform) in a short time window, an “intelligent” DBS system should detect fluctuations and adverse effects as well as more subtle pathophysiological changes and change settings accordingly without patients waiting until the next control visit for reprogramming (Priori et al. 2005a, b; Marceglia et al. 2007; Burgess et al. 2010; Rosin et al. 2011; Santaniello et al. 2011; Winestone et al. 2012).

aDBS is based on a feedback model that measures and analyzes a control variable related to the patient's clinical condition and changes the stimulation settings of an intelligent stimulator implanted in the chest (Welter et al. 2004; Priori et al. 2005a, b, 2013).

The control variable must be a physiological variable measurable in patients undergoing DBS, without implants other than those patients already carry (electrodes, extensions, and pulse generator), and able to reflect changes in the patient's condition.

For their ability to reflect clinical conditions, neuronal oscillations, measured through LFPs from DBS target structure, can be used as control variable. All the evidence summarized in the previous sections of this entry supports the choice of LFPs as control variable for aDBS: LFPs are recordable without additional implants, they correlate with the patient's clinical condition (Table 1), and they can be recorded during DBS on (Table 2), without artifacts (Rossi et al. 2007), and recorded over time after electrode implant (Rosa et al. 2010) showing DBS-induced modulations similar to those recorded a few days after electrode implant (Rosa et al. 2011).

At present, only external, research-oriented aDBS devices are available. Before the new aDBS systems can be implanted in patients, research should better define the control LFP-based biomarkers that best reflect the patient's clinical state, refine feedback algorithms, develop a prototype device for use in patients, and conduct a clinical study to compare the new aDBS system with the current "reference-standard" DBS system.

Definition

Local field potentials (LFPs) represent the sum of low-frequency electrical activities in the

extracellular medium close to a recording electrode. They predominately reflect field changes related to the flow of electrical current at synapses in the vicinity of the electrode, although other tissue components (neuronal spiking, glia potentials) may also contribute. The amplitude of LFPs is affected by the synchrony of dendritic potentials and by the geometry of dendritic arbors. Most of the electrical events that contribute to LFP signal occur within 200–400 μm of the tip of the electrode (Katzner et al. 2009; Xing et al. 2009).

LFPs can be recorded with microelectrodes, usually referenced against an electrode outside of the brain, or with macroelectrodes, usually as differential recordings between two poles of the same electrode. Because most of the spectral power of LFPs is found at relatively low frequencies (<300 Hz), LFP signals are often low-pass filtered (with a filter cutoff of 100 or 300 Hz). Most analyses of LFPs are done with frequency-domain analysis methods, dividing the signal into delta (0–4 Hz), theta (4–7 Hz), alpha (7–13 Hz), beta (13–30 Hz), and gamma (30–100 Hz) components.

Detailed Description

The literature on the role of local field potentials (LFPs) in movement disorders is extensive. In order to keep this review focused, we have chosen to limit our discussion to some representative results of recordings from the basal ganglia and related subcortical structures in human movement disorder patients. Animal studies and the results of cortical recordings are mentioned as appropriate, but are not covered in detail.

Before describing the results of LFP recording studies in movement disorders, we will briefly review the anatomy of the basal ganglia because most movement disorders involved changes of electrical activity patterns in these structures. The basal ganglia are subcortical components of several circuits that also involve the thalamus and cortex. Traditionally, at least four different segregated circuits are distinguished, including circuits involved in motor, oculomotor, associative, and limbic functions (Alexander et al. 1990). As

shown in Fig. 1, the basal ganglia are further divided into the striatum (putamen and caudate in primates), the subthalamic nucleus (STN), the external and internal segments of the globus pallidus (GPe and GPi), and the substantia nigra with its dopaminergic pars compacta (SNc) and the GABAergic pars reticulata (SNr). The STN and striatum receive monosynaptic projections from the frontal cortex (Akkal et al. 2007; Haynes and Haber 2013), while GPi and SNr are the

Local Field Potential and Movement Disorders, Fig. 1 The basal ganglia-thalamocortical motor network. *Black arrows* indicate inhibitory connections and *gray arrows* indicate excitatory connection. Structures marked in *gray* are frequently used for LFP recordings. The table at the *bottom* of the figure summarizes the principal findings in studies of frequency-domain analyses of LFP recordings in the diseases mentioned in the text. Abbreviations: CM centromedian nucleus of the thalamus, *dec.* decreased, *GPe* external segment of the globus pallidus, *GPi* internal part of the globus pallidus, *inc.* increased, *Pf* parafascicular nucleus of the thalamus, *PPN* pedunculopontine, *SNc* substantia nigra pars compacta, *SNr* substantia nigra pars reticulata, *STN* subthalamic nucleus, *VA* ventral anterior nucleus of thalamus, *VL* ventrolateral nucleus of thalamus. (Figure modified from Galvan and Wichmann (2008) and used with permission)

output nuclei of the basal ganglia, projecting to specific nuclei in the thalamus and brain stem.

As the basal ganglia receive excitatory input from the cerebral cortex and send (net inhibitory) output back to the cortex via the intercalated thalamus, the corticobasal ganglia-thalamocortical system is considered to function as an at least partially closed negative feedback loop (Joel and Weiner 1994). Among several other neuromodulators, the release of dopamine in the striatum strongly affects the function(s) of these loops. This neurotransmitter is involved in a variety of specific functions of the basal ganglia such as motor learning, response inhibition, or the facilitation of movement (Do et al. 2012).

Most of the classic movement disorders are associated with abnormal basal ganglia functions, and several involve altered dopaminergic transmission (Albin and Mink 2006). Recordings of LFPs in patients undergoing deep brain stimulation (DBS) surgery or in animal models of these diseases have mostly focused on the nuclei shaded in gray in Fig. 1. Studies in patients and in animal models have their respective advantages and disadvantages. While recordings in patients give direct information on the human disease, it is ethically impossible to obtain true control data from humans, and most patients undergoing surgery have received other therapies previously, which may affect the results of recording studies. LFP recordings in animals are far more controlled and can be obtained at baseline and during a variety of disease states. However, none of the animal models of movement disorders fully replicates the rich phenotype of the corresponding human disorders.

LFP Studies in Brain Diseases

Parkinson's Disease

While Parkinson's disease (PD) involves degeneration of neurons in many brain regions, the defining physical signs of the disease, i.e., tremor, bradykinesia, akinesia, and rigidity, are caused by the loss of dopaminergic cells in the SNc and the resultant degeneration of the dopaminergic projections between the SNc and the striatum and

other basal ganglia nuclei (and potentially cortex). The dopamine loss most severely affects components of the motor circuit of the basal ganglia, although other circuits are also affected. The loss of the dopaminergic innervation in the striatum is thought to lead to abnormal neuronal activity patterns throughout the basal ganglia and related areas in the thalamus and cortex (Galvan and Wichmann 2008).

Studies in human patients with advanced PD have shown that the disease is associated with prominent beta-band oscillations in LFP recordings from the STN (for review see Stein and Bar-Gad 2013), giving rise to the view that synchronized oscillations within the basal ganglia-thalamocortical network of connections are a key feature of PD. This notion is supported by the fact that beta-band oscillations are reduced by antiparkinsonian treatments such as dopaminergic medications or high-frequency stimulation of the STN (Bronte-Stewart et al. 2009; Brown et al. 2001; Kuhn et al. 2008; Levy et al. 2002; Priori et al. 2004; Wingeier et al. 2006). Increased beta-band oscillations have also been described to occur in GPi (Brown et al. 2001; Cassidy et al. 2002), and (presumably) abnormal delta- and theta-band activities have been found in the primary motor cortex of parkinsonian patients (Neufeld et al. 1994; but see Sebban et al. 1999; Serizawa et al. 2008; Soikkeli et al. 1991). Studies in dopamine-depleted (6-hydroxydopamine treated) rats have also documented an increase of the power of beta-band oscillations of LFPs in the basal ganglia (Avila et al. 2009; Mallet et al. 2008; Sharott et al. 2005).

While there is, thus, strong reason to believe that abnormal oscillations occur in the basal ganglia in severely parkinsonian humans or animals, it is less clear whether the oscillations (or the phenomena underlying them) *cause* parkinsonism. There is, in fact, evidence suggesting that beta-band activity in the STN contributes to akinesia (Kuhn et al. 2004; Williams et al. 2005), but other studies in humans failed to demonstrate a strong correlation between clinical impairments and STN beta-band activity (Kuhn et al. 2009; Ray et al. 2008; Weinberger et al. 2006; Zaidel et al. 2010a), and the effects of direct

stimulation of the BG in the beta range of frequencies, designed to mimic the effects of beta-band LFP oscillations, are only subtle (Chen et al. 2007, 2011; Eusebio et al. 2008). Furthermore, studies in parkinsonian monkeys have shown that the animals develop beta-band LFP oscillations only in late stages of parkinsonism, while less severe parkinsonism is not associated with increased beta-band oscillations (Devergnas et al. 2012).

The lack of a clear link between LFP oscillation and parkinsonism underlines that the recorded LFP oscillations are not likely to be pathologic per se but are a proxy for the presence of synchronized oscillatory single-neuron activities. Even if such synchronized single-cell oscillations are a primary pathophysiologic event (which has not been conclusively shown yet), the degree of oscillations and synchrony in the early stages of parkinsonism may simply not lead to recordable LFP oscillations.

Levodopa-Induced Dyskinesia

Choreiform dyskinesias are a side effect of long-term therapy with levodopa in approximately 50% of PD patients within 5 years of commencing levodopa therapy (Del Sorbo and Albanese 2008; Fahn 2000). Levodopa-induced dyskinesias (LID) are a major limitation of levodopa therapy and one of the principal reasons why patients with advanced PD seek surgical treatment, such as DBS applied to GPi or STN. Studies of LFP recordings in such patients showed that beta-band activity is reduced during periods of LIDs, while spectral peaks around 9 and 70 Hz are prominent (Alonso-Frech et al. 2006; Weinberger et al. 2012). The reduction of beta-band activity and the increase in high gamma-band oscillations (around 70 Hz) resemble the levodopa-related responses in non-dyskinetic PD patients, suggesting that these peaks are not specifically related to LIDs (Brown et al. 2001; Williams et al. 2002). However, the 9 Hz peak during LIDs is similar to what was found in the GPi LFP recordings from patients with dystonia (see below) and may, thus, represent an LFP oscillation signature of involuntary movements (Liu et al. 2002). This hypothesis is further supported by a finding of increased coherence at frequencies

below 10 Hz in a patient contralateral to unilateral dyskinesias, compared to the other side (Foffani et al. 2005). As mentioned above, such results do not prove causation; the low-frequency oscillatory activities may simply indicate an altered network state that is conducive to involuntary movement.

Dystonia

Dystonia is characterized by intermittent and sustained muscle contraction, often involving co-contraction of agonist and antagonist, which leads to involuntary abnormal movements and postures. Dystonia is often associated with an increase of low-frequency oscillations (<12 Hz) in LFP recordings from the basal ganglia of patients undergoing DBS lead placement procedures, particularly in the GPi (Chen et al. 2006b; Liu et al. 2002; Silberstein et al. 2003; Weinberger et al. 2012). The LFP oscillations correlate with oscillations found in EMG recordings (Chen et al. 2006a; Liu et al. 2006). Furthermore, a reduction of low-frequency GPi LFP oscillations was found to accompany alleviation of dystonia by use of “sensory tricks” (Tang et al. 2007).

As in the other disease models mentioned, a causal link between oscillations and phenotype is not certain, but, based on the cited observations, it is possible that low-frequency neuronal oscillations in the pallidum drive dystonic muscle contractions or contribute to abnormal processing of afferent information at the pallidal (or striatal) level. Unfortunately, there are few convincing animal models of dystonia, so that a detailed study of the pathophysiologic significance of the oscillatory activity is not possible at the moment. However, in one of the available models, the *dt^{sz}* mutant hamster, increased low-frequency LFP activity in the pallidum was, indeed, identified during and between paroxysms of dystonia (Gernert et al. 1998).

Essential Tremor

Unlike the previous entities in this entry, essential tremor is a movement disorder that does not seem to be directly dependent on abnormal basal ganglia activity or on changes in dopamine release in the basal ganglia. Essential tremor often occurs in families and usually manifests as an asymmetric

action tremor at 4–12 Hz, predominantly involving the hands or head, and not accompanied by major other neurological signs, with the possible exception of mild gait disturbances and some cognitive dysfunctions (Raethjen and Deuschl 2012). Most patients gain satisfactory control of their tremor with medications. Patients with medication-resistant disabling ET benefit from ablative or stimulation treatment, usually directed at the ventral motor nuclei of the thalamus. Although it has proven difficult to convincingly identify a central oscillator that causes the tremor, several lines of evidence have implicated the olivocerebello-thalamic system in its pathophysiology (for review see Raethjen and Deuschl 2012). Studies in this field have shown that the action tremor is associated with excessive theta-alpha activity in the cerebello-thalamocortical network (Air et al. 2012). An early study found LFP oscillations in the cerebellar-receiving nuclei of the thalamus in the 8–27 Hz range in patients with either ET or cerebellar outflow tremor (Marsden et al. 2000). Llinas et al. (1999) suggested that ET movements represent the product of abnormal cross frequency modulation, in which low-frequency thalamic oscillations would influence the generation of pathologic beta or gamma activity (Llinas et al. 1999). A more recent examination of inter-frequency correlation (or modulation) of the LFPs recorded in the motor thalamus of patient with ET corroborated this view (Kane et al. 2009).

Tics

Tics are stereotyped sudden movements, vocalizations, or complex behavioral acts. In marked distinction to other hyperkinetic movement disorders, tics are associated with a premonitory urge and can be temporarily suppressed. While tics are a very common and usually well tolerated, severe tics can significantly interfere with behavior. Additional disability results from the fact that severe tics are frequently associated with obsessive-compulsive symptoms, as is often the case in cases of Tourette syndrome (TS). TS is generally seen as a neurodevelopmental disorder that involves motor and limbic corticobasal ganglia-thalamocortical circuits, specifically networks involving orbitofrontal and prefrontal

dorsolateral cortices (Kalanithi et al. 2005; Worbe et al. 2012).

LFP recordings from the ventralis oralis complex of the thalamus done in TS patients who underwent surgical treatment for their symptoms, and who did not have tics during the recording, showed peaks of oscillatory activity in the 2–13 Hz range (Marceglia et al. 2010). Similarly, a comparison between recordings from a patient with mild tics with recordings from a population of patients with severe tics leads to the suggestion that the amplitude of low-frequency thalamic oscillations may be related to tics (Priori et al. 2013b). Other studies have suggested that the power in the gamma band (30–40 Hz) in LFP recordings from the centromedian thalamic nucleus is positively correlated with tic improvement after high-frequency stimulation (Maling et al. 2012).

LFP changes related to tic-like movements have also been seen in studies in rodent and monkeys (Darbin and Wichmann 2008; Marsden et al. 1975; Muramatsu et al. 1990; Nakamura et al. 1990; Yoshida et al. 1991) in which pharmacologic blockade of striatal GABA receptors resulted in rhythmically recurring stereotypies. These abnormal movements have been variously interpreted as myoclonus, dyskinesias, seizures, or, most recently, as tics (McCairn et al. 2009, 2013; Worbe et al. 2009, 2013). It has been shown that striatal injections of GABAA receptor antagonists lead to high-amplitude LFP activity and burst spiking of interneurons and projection neurons in the striatum (Darbin and Wichmann 2008; Muramatsu et al. 1990; Nakamura et al. 1990; Yoshida et al. 1991), cortex, and cerebellum (Darbin and Wichmann 2008; McCairn et al. 2013). Based on these and other results, it has been hypothesized that tics may result from the sudden regional failure of intra-striatal inhibitory processes (Albin and Mink 2006), leading to local synchronization of striatal activity, local oscillatory activities (detectable in LFP recordings), and the release of unintended movements. Individual patients usually have very stereotypic tics, suggesting that the specific tic phenotype is caused by a regionally specific abnormality in the somatotopically highly organized striatum.

Huntington Disease

Huntington disease (HD) is an autosomal dominantly inherited neurodegenerative disorder that characteristically leads to chorea (defined by jerky, random, and uncontrollable movements) as well as emotional symptoms and cognitive decline. The chorea is thought to result from striatal pathology and disturbances of corticostriatal transmission (Walker 2007). Although a variety of transgenic rodent models exist, most do not replicate the motor phenotype of HD.

LFP studies are very limited in this field. Two studies, utilizing the rapidly progressive R6/2 huntingtin-overexpressing strain of mice, revealed the presence of aberrant striatal LFP oscillation in the delta, theta, and gamma bands. At rest, striatal activity was characterized by prominent gamma band (30–40 Hz) in the “HD” group compared to control animals. With increasing behavioral demands (for instance, during episodes of exploration), the abnormally high corticostriatal coherence in the gamma range of frequencies is normalized (Hong et al. 2012; Miller et al. 2011).

A small number of HD patients with devastating motor symptoms have undergone surgical ablative or stimulation treatments, targeting GPi (Biolsi et al. 2008; Hebb et al. 2006; Moro et al. 2004). In one such study (Groiss et al. 2011), involving a patient with gene-testing-confirmed HD, LFPs in the motor portion of GPi showed strong oscillatory power in the 4–12 Hz and in the 35–45 Hz range close to the effective DBS target site. This preliminary result is in line with the cited data from the HD mouse model, implicating low gamma-band LFP oscillations in the pathologic process. The increase in 4–12 Hz oscillation activity in GPi resembles that in other hyperkinetic disorders (see above and Silberstein et al. (2003)).

Significance and Use of LFP Recordings in Movement Disorder

There remains great uncertainty with regard to the generation of LFPs and their ultimate pathophysiologic relevance in movement disorders. As mentioned above, LFPs strongly reflect postsynaptic

potentials in ensembles of cells. LFPs are therefore often taken as measures of inputs to the brain area from which the LFPs are recorded. The amplitude of LFPs in given brain regions is also a function of the specific cellular arrangements of cells in the studied area. For instance, the regular laminar arrangement of the cerebral cortex favors the generation of large-amplitude LFP signals, while the irregular arrangement of basal ganglia neurons results in smaller LFP amplitudes because electrical field are canceling each other out under these circumstances.

The synchrony or temporal correlation between inputs to the area under study is another factor that determines the amplitude of LFP signals. Synchronous inputs to a given brain area do not only lead, via summation, to larger LFP amplitudes but are also more likely to cause spiking activities than asynchronous inputs. The amplitude of LFPs is therefore not only an indicator of the synchrony of inputs to the recorded brain area but also a measure of correlated activities of the neurons that receive the inputs at the recording site (Goldberg et al. 2004). Other physiologic phenomena that may be related to synaptic activities (for instance, changes in blood flow (Magri et al. 2012)) are also related to LFP amplitudes.

Measurable LFP oscillations may arise if the disease process in question causes abnormal oscillatory activities of ensembles of neurons in the basal ganglia or in structures anatomically linked to them (Bevan et al. 2002; Plenz and Kital 1999). Alternatively, it is possible that an increase in synchrony between neurons affects certain frequency bands more than others, leading to resonance phenomena in these frequency bands. Such changes could occur and could alter LFP oscillations, even if individual neurons do not alter their activity significantly (see, e.g., Terman et al. (2002)).

LFP recordings do not only provide a convenient tool to learn more about the pathophysiology of brain disorders but can also be used to guide and expedite surgical procedures. Currently, electrophysiologically guided neurosurgical procedures rely on lengthy single-cell recordings with microelectrodes which are then

exchanged for the DBS (or lesioning) probes toward the end of the intervention. The use of LFP recordings may be a favorable alternative to the single-cell recordings, shortening the procedure and reducing targeting errors. In fact, some authors have started to explore the use of spectral analysis of intraoperatively recorded LFPs (while advancing DBS electrodes into the brain) to guide electrode placement, particularly in the STN (Chen et al. 2006c; Miyagi et al. 2009). For example, in PD patients, beta-band activity was found to increase progressively during the electrode descent and was maximal at the target (Chen et al. 2006c). This result was confirmed by Miyagi et al. (2009) who found an increase of power in the theta, alpha, and beta bands a few millimeter above the dorsal border of the STN (Miyagi et al. 2009). The spatial resolution of contemporary methods of LFP-based targeting is not fully sufficient, however, and needs to be further improved before it can be recommended as a replacement for microelectrode recording (Zaidel et al. 2010b).

Another exciting application of our emerging knowledge of LFP oscillation patterns is the use of disease-related LFP characteristics to regulate DBS parameters in “closed-loop” feedback regimes. Such adaptive DBS strategies may allow us to better control fluctuating or transient disease manifestations, reduce stimulation-related side effects, and prolong the battery life of the implanted devices (for review see Priori et al. 2013a). Closed-loop modulation of stimulation has already been used in clinical trials for refractory epilepsy (Fridley et al. 2012) where short-term stimulation can be triggered based on analyses of brain activity patterns that predict or signify seizures. Closed-loop control of DBS devices in movement disorder patients is more difficult, because the correlation between the recordable electrical signals and the severity of disease symptoms is generally weak and because DBS in these disorders is usually continuous rather than episodic as in epilepsy patients. It remains challenging to obtain reliable LFP recordings in the face of stimulation artifacts produced by ongoing stimulation. However, the general feasibility of closed-loop approaches in

movement disorder cases has been demonstrated with computational modeling studies (Santaniello et al. 2011) and with experimental studies in which cortical (single neuron) activity patterns were used to trigger STN stimulation in parkinsonian monkeys (Rosin et al. 2011). Very recently, adaptive deep brain stimulation has been used in PD patients, demonstrating greater efficacy and lower power consumption than achievable with conventional open-loop stimulation (Little et al. 2013). The authors of this study used short-term changes in beta-band LFP power (lasting less than 1 s) to trigger the stimulation, based on previous work showing that motor impairments were correlated with beta-band stability in the STN (Little et al. 2012). These results are promising, but the signal analysis and control of the DBS device still required an external computer, and the miniaturization (and *overall* power consumption) of an implantable closed-loop system remains an issue (Starr and Ostrem 2013).

Conclusion

Even if the functional significance of LFP oscillation remains unclear, the ready availability of LFP recordings from both human and animal sources has greatly increased our understanding of movement disorders and other diseases. The discussed disease examples suggest that abnormal basal ganglia oscillations in the delta-alpha range of frequencies are common in patients with hyperkinetic disorders, as well as in animal models of these conditions, while LFP oscillations in the beta band characteristically accompany parkinsonism. Fortunately, even in the absence of unifying pathophysiologic hypotheses to explain the generation of specific LFP patterns, the characteristics of the recorded signals may be empirically used to improve the outcome of surgical interventions. It is important to remember in these efforts that the current focus on frequency-domain features of LFPs is largely driven by the ease with which such characteristics can be analyzed. It may be fruitful to extend the analytical repertoire in the future to also capture feature in the time domain, such as nonlinear characteristics.

Acknowledgments This review entry was supported by grants from the National Institute of Health and National Institute of Neurological Disorders and Stroke R01-NS054976 and P50-NS071669 as well as an infrastructure grant from the NIH to the Yerkes Center (P51-RR165, now P51-OD11132).

Local Field Potential Decoding

► Decoding Field Potentials

Local Field Potential in the Visual System

Gregor Rainer
Section of Medicine, University of Fribourg,
Fribourg, Switzerland

Definition

Low-frequency component of the continuous time-varying electrophysiological signal recorded using intracranial extracellular electrodes placed

inside the visual cortex. It is dominated by local cooperative activity of neural networks occurring in a volume of tissue around the tip of the electrode.

Detailed Description

Biophysical Origin

It is thought that the main contribution to the local field potential (LFP) derives from synchronous activation of neurons in the surrounding cortex. The LFP represents the sum over typically many thousands of local electrical fields that are generated within individual neurons. When a neuron is activated by the arrival of an excitatory postsynaptic potential on its dendrite, charged ions pass through its membrane which normally acts as an electrical insulator (Eccles 1951). An inflow of positive ions is termed current sink by convention, whereas an outflow of positive ions is termed current source. Since inflowing positive ions must be compensated for by an appropriate outflow of positive ions, there must be a current source corresponding to every sink. While current sinks reflect membrane depolarization and neuronal excitation, current sources can, for example, result from hyperpolarization or the action of ionic pumps of the neuron that restore the membrane potential to its equilibrium value. The spatial separation between sources and sinks during neural activation gives rise to an electrical dipole within each neuron, whose magnitude depends on the transmembrane ionic flow. The geometry of neural dendrites determines whether a measurable LFP signal is generated from the dipoles within individual neurons. If all neurons had symmetric “closed-field” dendritic geometry or exhibited randomly oriented dendritic trees, then individual electrical dipoles would tend to cancel each other, and no LFP signal could be measured. However, pyramidal neurons of the cortex exhibit an “open-field geometry,” such that their apical dendrites are all aligned parallel to each other and perpendicular to the cortical layer structure. This causes an alignment of the electrical dipoles in these pyramidal cells when these are synchronously activated, which permits their summation and in turn generates a robust LFP signal.

In addition to synaptic contributions described above, there are a number of additional factors that can influence the LFP. For example, intrinsic properties of the membrane may exhibit resonance such that depolarization or activation of the neuron results in a self-sustaining voltage oscillation (Silva et al. 1991). Other neuronal events have also been shown to contribute to the LFP, including direct electrical communication between neurons via gap junctions (Traub et al. 2004), interactions between neurons and glial cells (Poskanzer and Yuste 2011), and potentially also dendritic calcium spikes. Unlike the action potential, which has a clear functional role as transmitting information from one neuron to another, the LFP is not thought to have a direct role in information processing or transmission. Because of this, it has been sometimes considered to be a mere epiphenomenon. However, in recent years interest in the LFP has accelerated, and it is now widely considered to be a signal that provides useful information about the local processing that occurs in the cortical volume near the electrode tip. In part, this resurgent interest stems from studies that have linked hemodynamic signals, including the functional magnetic resonance imaging (fMRI) signal that is extensively used to study human cognition, to aspects of the LFP (Logothetis 2003; Niessing et al. 2005). An interesting and hitherto largely unexplored issue is whether the LFP itself exerts any ephaptic influence on neural processing, such that the extracellular voltage fluctuations of the LFP might be sensed by local neurons and in turn influence, for example, their excitability. This remains an open issue, but studies using transcranial magnetic stimulation have indeed shown that the electrical gradients of the LFP are within a range that can affect action potential generation and cognitive behavioral performance (Marshall et al. 2006; Ozen et al. 2010).

Characteristics

The LFP often exhibits oscillations, and these are traditionally classified into separate frequency bands on the basis of characteristic behavioral states associated with each band. These bands,

together with the approximate frequency range, are delta (0–4 Hz), theta (4–8 Hz), alpha (8–12 Hz), beta (12–20 Hz), and gamma (20–80 Hz). These bands are also used for analysis of the electroencephalographic (EEG) signal, and the LFP is in fact closely related to the EEG but has superior signal-to-noise ratio and spatial specificity, since it is not subject to the filtering of electrical signals by the skull. The LFP, in similarity to all neurophysiological brain signals, is stochastic, and each repetition of a particular experimental condition yields a distinct time series. During a typical neurophysiological study, about ten repetitions are conducted per experimental condition. Averaging of all repetitions for a given condition yields the visual evoked potential (VEP), which generally consists of a number of positive and negative deflections in a time range between about 30 ms and 400 ms after the presentation of a visual stimulus. The time of the first observable VEP deflection is called visual response latency and represents the time of arrival of visual signals from the eye via the visual pathway. Subsequent VEP deflections are related to local processing of the visual signals within the neural circuits of the visual cortex. To further characterize the VEP, the approach of current source density (CSD) estimation has been introduced (Mitzdorf 1985) and is commonly applied in the analysis of VEP signals. CSD estimation requires VEP signals to be recorded from multiple layers of the cortex, which can be achieved by successively advancing a recording electrode through the layers or by employing a multi-contact depth electrode capable of simultaneous recording of LFP signals from the six layers of the cortex. The CSD of a small-volume element of the cortex can be written as the divergence of the current flow from that surface element under the assumption of an ohmic medium:

$$\text{CSD}(\mathbf{x}, \mathbf{y}, z) = -\nabla(\sigma \nabla \Phi(\mathbf{x}, \mathbf{y}, z)),$$

where σ is the conductivity tensor and $\Phi(\mathbf{x}, \mathbf{y}, z)$ is the field potential.

Under the assumptions of dendrites being elongated in the vertical (z) direction and therefore

current flowing mainly along this dimension, as well as homogenous conductivity medium, this reduces to:

$$\text{CSD} = -\sigma_z \frac{\partial_2 \Phi}{\partial^2 z}$$

Note that homogeneity of conductivity is only approximately true, since the cerebral spinal fluid (CSF) surrounding the brain exhibits about five times higher conductivity than cortical gray matter. This of course means that the above solution is distorted particularly if large reservoirs of CSF are nearby, as is the case in brain structures close to the ventricles.

Using a three point approximation of the second derivative, this results in the following equation for the CSD:

$$\begin{aligned} \text{CSD}(z, t) &\approx \frac{\partial_2 \Phi(z, t)}{\partial^2 z} \\ &\approx \frac{\Phi(z + h, t) - 2\Phi(z, t) + \Phi(z - h, t)}{h^2} \end{aligned}$$

Thus, the CSD value at cortical depth z and time t can be written as a sum of the experimentally determined VEP value Φ at that depth z and at cortical depths above ($z - h$) and below ($z + h$). Under the assumptions described above, the CSD provides information about in which layer of the cortex outward positive ion flow or sources occurs, as well as about the laminar location of extracellular sinks.

The VEP and CSD estimates consider only those portions of the LFP that are time-locked to the onset of a visual stimulus, whereas LFP deflections whose timing varies from one repetition to the next are lost in the averaging process. To faithfully estimate these components, the LFP is first band-pass filtered in an appropriate frequency band, and then the estimates of the power in this band on all repetitions of a particular condition are averaged. LFPs are generally measured against a ground position that is far away from the visual cortex, for example, a metal skull screw over the frontal cortex, and are typically in the range of about $\pm 100 \mu\text{V}$.

Primary Visual Cortex (V1) Visual Evoked Potential (VEP)

The primary visual cortex is the cortical area that receives visual information from the retina via the lateral geniculate nucleus of the thalamus, with most projections arriving in the thalamocortical recipient layer 4 and some also in layer 6. From layer 4, which is often referred to as the granular layer due to the presence of granular cells in this layer, visual signals are sent to the supragranular layers 2 and 3 where they are processed further by cortical circuits (Douglas and Martin 2007). These supragranular layers are the main site of cortico-cortical information exchange and are thus involved both in sending and reception of signals from higher-order cortical areas. In the case of primary visual cortex, strong reciprocal projections exist, for example, with extrastriate visual cortical areas such as V2 or V4. The highly recurrent nature of cortical function generally complicates the interpretation of VEP signals, since these are influenced not just by bottom-up inputs from the ascending visual pathways but also by recurrent feedback from higher visual areas. The earliest VEP deflections are however thought to be determined by the ascending inputs. For example, in macaque monkey V1, the VEP displays a number of features that are related to these anatomical structural characteristics (Schroeder et al. 1998). Accordingly, strongest responses, in terms of VEP deflections and CSD values, occur in thalamo-recipient layer 4 of the cortex, and both layer 4 and layer 2/3 exhibit an initial current sinks consistent with neural activation by the feed-forward pathway. An interesting aspect of the V1 VEP is a prominent reversal of polarity in the early prominent VEP deflection occurring around 50 ms between layer 4 and layers 5/6 that can be used as a marker to estimate the border between granular and infragranular recording sites during neurophysiological experiments. Using the V1 VEP as a measure of response latency in terms of the earliest detectable change of the VEP signal yields values of about 30 ms, considerably larger than corresponding values of about 15 ms observed in the visual thalamus.

Higher Visual Cortex Visual Evoked Potential (VEP)

VEPs invariably accompany spiking activity in response to visually presented stimuli, not only in V1 but also for other brain regions that are part of the visual system, including the extrastriate visual cortex, the inferior temporal and parietal cortices, as well as certain areas of the prefrontal cortex where visual information is used for guiding action. Since synaptic activity is the major determinant of the LFP, this signal provides information about the source of these synaptic inputs. For a cortical neuron, the input source comes mostly from the same cortical column by way of recurrent local connectivity, as well as to a lesser degree from brain regions that send projections to the neuron under study. Conversely, local action potential activity is related mainly to local recurrent processing but also carries the information that is sent from the region under study to distant targets. Following this logic, comparison of timing and task-related information present in LFP and spiking activity can be used to infer the location of neural computations. For example, if task-related signals are present in spiking activity before they are observable in the LFP, this strongly argues for a local computation of this information in the brain region under study (Monosov et al. 2008; Nielsen et al. 2006).

Visual Cortex LFP: Spatial Specificity

A pertinent question related to LFP signals is their spatial specificity, reflecting the degree to which they represent local activation within a region of cortex rather than mirroring activation that actually occurs at a distant site. Electrical signals observed locally may thus be due to transmitted potentials from distant sources, in a process that is termed volume conduction. The degree to which LFP signals in the visual cortex are of local origin is a subject of current debate. On the one hand, various evidences related to EEG recordings suggest that volume conduction can occur and electrical signals can be picked up in scalp recordings from sources that are known to be far away from the recording location (Cobb and Sears 1960; Jewett and Williston 1971). Similarly, LFP recordings in the cortex have also shown that

signals generated in one area of the cortex can spread to regions a centimeter or more away. For example, LFP signals related to auditory stimuli were greatest in amplitude within the primary auditory cortex itself, and the amplitude declined approximately linearly with increasing distance such that 12 mm away a signal of about 5% of the peak magnitude could be picked up (Kajikawa and Schroeder 2011). Notably, the LFP spread in this study was measured in the z-axis, parallel to the apical dendrites and perpendicular to the cortical layer structure. These results were obtained in the auditory cortex, but it is highly likely that similar volume conduction occurs also in the visual cortex but is probably more difficult to observe there due to the close proximity of multiple visual areas in the occipital lobe of the brain that each generates VEPs in response to visual input. Other studies have estimated LFP spread to be up to two orders of magnitude lower, with values between 250 and 600 μm . In one study, a high-resolution map of orientation selectivity of a V1 patch was obtained (Katzner et al. 2009) using voltage-sensitive dye-based optical imaging, by presenting a visual-oriented grating stimuli large enough to activate the entire cortex being imaged in pseudorandom order. The resulting map was then used to predict LFP orientation selectivity at particular grid nodes of the map using different two-dimensional Gaussian spread standard deviation values. When these predicted LFP orientation selectivity values were compared to LFP measurements, the optimal fit occurred for a standard deviation of about 100 μm , which translates to over 95% of the LFP being generated within a radius of 250 μm . In another study, action potential activity, the so-called multiunit activity (MUA), was recorded simultaneously with LFPs in the visual cortex during the presentation of a sparse noise visual stimulus, where small spots of light on a rectangular grid are successively and individually illuminated in a pseudorandom order (Xing et al. 2009). This allows the determination of the spatial spread of both MUA and LFP activities, yielding an average value of 250 μm . Interestingly, spatial spread was lowest for the thalamocortical input layer 4 (150 μm) and relatively highest in the supragranular layer 2/3

(280 μm). Notably, for both cited studies, the LFP spread of 250 μm was estimated in the horizontal (x-y) direction, parallel to the cortical layer structure, which represents a difference compared to the above spread estimate of 1 cm or larger that is based on measurements in the z-direction. Another possible explanation is that LFP integration has been shown to be dependent on the contrast of the stimulus, which is related to the strength of the sensory input. For low-contrast stimuli of relatively weak strength, LFPs tended to be correlated across relatively large distances of 1 mm or more, whereas for high-contrast stimuli, they were more localized (Nauhaus et al. 2009). It is however unclear whether these factors really are the source of the discrepancy in the literature regarding the spatial selectivity of LFP signals. Other potential sources include differences in sensory stimulus characteristics, details concerning data analysis procedures, and experimental data acquisition such as location of the ground or hardware filtering as well as potential capacitive cross talk between channels on multichannel recording probes.

Visual Cortex LFP Oscillations: Locking to External Stimulus

The visual cortical LFP, similar to spiking activity, reflects temporal characteristics of the visual input up to frequencies approaching 90 Hz. Visual displays with deterministic timing characteristics, such as cathode ray tube and some LED displays but not most TFT monitors, can be operated at different refresh rates. For refresh rates up to about 90 Hz, visual LFP signals are highly entrained to this refresh rate and display oscillatory power in the corresponding frequency band during periodic visual stimulation (Veit et al. 2011; Williams et al. 2004). The appearance of the corresponding peaks at the refresh rate and higher harmonics in the LFP spectral analysis is thus not due to intrinsic cortical mechanisms but is driven by the external stimulus and must be interpreted as such. These oscillations are visible in the average VEP only if timing is monitored with millisecond precision which generally requires additional verification using a light-sensitive diode. For refresh rates above 90 Hz, the neural response is no longer

strongly phase locked to the visual display refresh and approximates the response to a real-world object that emits continuous rather than pulsed light.

Visual Cortex LFP Oscillations: Gamma Band

In addition to these oscillations that result from the visual display procedures, the visual LFP also exhibits various oscillations in different frequency bands that are generated intrinsically by the brain and can be linked more or less closely to perceptual or cognitive phenomena. Oscillations in the gamma (20–100 Hz) range occur in the visual cortex during sensory stimulation, as is demonstrated either by enhanced broadband gamma activity or by the appearance of specific spectral peaks in the gamma range when one compares periods of visual activation to spontaneous activity (Eckhorn et al. 1988; Gray et al. 1989). Of the different LFP frequency bands, the gamma band is most closely linked to locally generated action potentials. Elevated spiking is thus often accompanied by the appearance of gamma oscillations in the LFP. Several studies have provided evidence linking gamma oscillations to perceptual processes such as temporal expectation and perceptual grouping (Lima et al. 2010; Lima et al. 2011) which are essential for object vision. Gamma oscillations have also been described in higher-order visual cortices (Grothe et al. 2012; Taylor et al. 2005), generally with an involvement in similar cognitive and perceptual functions as have been associated with V1 gamma. In addition, the phase of the gamma cycle is related to the exact spike timing, such that action potentials tend to appear preferentially during the downward slope and trough of the gamma cycle, with the precise phase relationship varying from neuron to neuron. It has been suggested that this phase locking of spike timing to the gamma cycle may provide a mechanism for optimizing information transmission from primary visual cortex to high visual centers, because spikes arriving simultaneously at postsynaptic targets will generate summing excitatory postsynaptic potentials and thus increase the probability of activating the postsynaptic target neuron compared to a case where inputs arrive uniformly distributed on a gamma

cycle. Indeed, gamma oscillations in extrastriate area V4 have been linked to attention, such that a patch of the cortex that is processing an attended visual stimulus exhibits enhanced gamma oscillations compared to a similar patch of cortex that is processing an identical unattended stimulus (Fries et al. 2001). In the inferior temporal cortex, gamma has also been described and implicated, for example, in perceptual awareness, albeit using recordings from the surface of the cortex (Fisch et al. 2009). Gamma oscillations can thus be considered to be an extremely widespread phenomenon in the visual system and may serve different functions in a brain-region-dependent manner. There is also some evidence suggesting that gamma oscillations may be more strongly coupled to feed-forward processing, i.e., signals sent from primary to extrastriate visual cortex, rather than feedback processing (van Kerkoerle et al. 2014). However, it has also been emphasized that gamma oscillations tend to be highly variable from trial to trial, such that there remains considerable doubt as to the degree to which they serve as a robust encoding mechanism for information processing (Ray and Maunsell 2010; Ray and Maunsell 2015).

Gamma oscillations are thought to originate locally in the cortex through coordinated interaction between excitation and inhibition (Buzsaki and Wang 2012) and generally require thalamocortical activation by a sensory stimulus. Evidence for local generation comes, for example, from the observation that gamma enhancements vary substantially as a function of cortical layer, with the thalamocortical input layer exhibiting much weaker gamma compared to the supragranular layer 2/3 (Xing et al. 2012). The generation of visual cortical gamma oscillations can be influenced by long-range projections from other brain areas that send axons to the visual cortex. One example is the basal forebrain, which provides a source of cholinergic, GABAergic, as well as glutamatergic inputs to the visual cortex. Thus, electrical stimulation of the basal forebrain generates gamma oscillations in V1, and both spectral peaks and broadband enhancements of gamma activity have been observed (Bhattacharyya et al.

2013). While local in nature, gamma oscillations are under the control of nonvisual brain structures, which can thus modulate the transmission of information about the visual environment to higher cortical centers.

While gamma oscillations and action potential spiking activity are closely related, this should not be taken to mean that these signals provide identical information. When spiking and LFP activity are directly compared in terms of their selectivity for orientation, one can observe that single unit as well as multiunit spiking activity at a given site is generally much better tuned for orientation than the gamma-band LFP (Berens et al. 2008). In addition, the orientation preference of gamma activity at a given recording site does not accurately predict the orientation preference of local action potential spiking activity. This observation is generally consistent with the above findings related to the spatial spread of the LFP, because adjacent neurons in the visual cortex can have drastically different orientation.

Visual Cortex LFP Oscillations: Other Bands

There are relatively few reports of beta oscillations in the visual system, and to date no clear functional role in visual processing appears to have emerged for LFP oscillations in this frequency range. In contrast, beta LFP activity plays an important role in the motor cortex and has been linked closely to spiking activity for motor control processes (Witham et al. 2007). Alpha oscillations are classically associated with cortical idling and appear, for example, in the visual cortex when the eyes are closed in the absence of a behavioral task. In contrast, the theta band appears to play an important role in short-term memory and structuring cortical communication over long distances. For example, intermediate extrastriate visual cortical area V4 exhibits characteristic oscillations in the theta frequency band that are linked to short-term memory and thus appear during behavioral tasks that include a delay period during which a previously presented visual stimulus needs to be maintained in memory (Lee et al. 2005; Raghavachari et al. 2006). The phase of the theta – like

gamma – oscillations is related to action potential timing, such that theta can structure information transfer with higher-order visual cortices. Indeed, simultaneous recordings have confirmed that during short-term memory there is in fact enhanced coupling between visual and prefrontal cortices, suggesting an important role of theta oscillations in maintenance of short-term memories (Liebe et al. 2012). At the same time, the role of theta oscillations extends beyond encoding and maintenance aspects of visual information. This has been documented, for example, in the rat, where visual stimulus-induced theta oscillations are closely related to precision and timing of reward-seeking responses (Levy et al. 2017). Theta oscillations in the visual cortex are thus related to long-range coordination of neural activity related to visual information encoding and maintenance, as well as other task-relevant information.

Local Field Potential, Ephaptic Interactions

Costas A. Anastassiou

Allen Institute for Brain Science, Seattle, WA, USA

Detailed Description

Charge transfer across the membrane of all structures in brain matter such as neurons, glial cells, etc. induces the so-called extracellular sinks and sources that, in turn, give rise to an extracellular field, i.e., a spatial gradient of the extracellular voltage (V_e) measured in comparison to a distant reference signal. The physics governing such events are described by Maxwell's equations. In their simplest form, Maxwell's equations dictate that V_e depends on the transmembrane current amplitude, the impedance of the extracellular medium, and the distance between the location of the ionic flux and the recording (see also entries ► [“Local Field Potentials: LFP”](#) and ► [“Local Field Potential, Methods of Recording”](#) and (Koch 1999)). V_e signals resulting from the activity of the entire cell populations can therefore be recorded via standard recording techniques and have been used for decades to monitor electric processing in the brain (Buzsaki 2002).

From *in vivo* electrophysiology studies, we know that the hallmark of a living brain is the presence of dynamic extracellular fields giving rise to continuous V_e fluctuations (see entries ► [“Local Field Potential, Relationship to BOLD Signal”](#) and ► [“Electrocorticogram \(ECoG\)”](#)). The strength and frequency content of such V_e fluctuations is highly dependent on a number of features such as the animal's behavior, the brain structure, the V_e bandwidth of interest, and the recording methodology employed (Buzsaki et al. 2012). For example, during various behavioral states such as running, the so-called theta activity gives rise to highly coordinated V_e oscillations observed along rat CA1 pyramidal layer of approx. 0.1–0.3 mV amplitude, while V_e oscillations of larger amplitude and roughly opposite polarity are concurrently recorded in hippocampal

CA1 stratum radiatum (Kamondi et al. 1998). During events related to memory formation such as hippocampal sharp waves, while V_e amplitude in CA1 pyramidal layer remains small (approx. 0.1 mV), V_e amplitude in stratum radiatum can reach 1–2 mV (Ylinen et al. 1995). The strength of electric fields in rat CA1 as measured with high-density silicon probes during theta is approx. 1–5 mV/mm, while during sharp waves, they can reach approx. 30 mV/mm. Finally, during pathological functioning of the brain such as in epileptic seizures, electric fields as strong as hundreds of mV/mm have been measured.

Neuroscientists have typically used V_e recordings to monitor the brain and infer modes of neural circuitry by studying the spatiotemporal features of V_e . This is typically defined as the “feedforward” process (e.g., see entry ► “Local Field Potential in the Visual System”). Yet, the neural membrane is affected by the presence of extracellular fields. A crude example is the strong entrainment of the neural membrane voltage (V_m) and, eventually, spiking observed during and/or immediately after electric stimulation, for instance, in electric microstimulation studies (entraining one or a few neurons (Tehovnik et al. 2006; Histed et al. 2009)) or deep brain stimulation therapy (entraining the entire neural circuits and brain regions (Mayberg et al. 2005; Lozano et al. 2008)). Defined as the difference between the intra- (V_i) and extracellular voltage (V_e) at a given time t and location $\mathbf{x}$, the membrane voltage $V_m(\mathbf{x}, t) = V_i(\mathbf{x}, t) - V_e(\mathbf{x}, t)$ will be affected by changes in $V_e(\mathbf{x}, t)$, i.e., the presence of extracellular fields. In effect, extracellular fields along the cable-like structure of neural morphology act as intracellular current injections at the ends of these cables, leading to alterations in their membrane potential (Ranck 1963a, b; Chan and Nicholson 1986; Chan et al. 1988; Holt and Koch 1998; Anastassiou et al. 2010).

Do dynamic, endogenous electric fields in the brain serve a functional role by altering the functioning of neurons? Can spatiotemporal fluctuations of the extracellular field influence via purely electrostatic, the so-called *ephaptic coupling*, (The term “ephapse” from the Greek word $\varepsilon\varphi\acute{\alpha}\psi\eta$ (i.e., the touch or junction) was coined by

Arvanitaki (1942) to describe electric field interactions occurring between juxtaposed axons. Over the years researchers have used alternative terms such as “electric field effects” to describe the same phenomenon. To date, the most detailed review about ephaptic coupling remains the seminal paper by Jefferys (1995). For a more recent review, see Weiss and Faber (2010)) the activity of individual neurons and neural populations? Such coupling would, thus, be a “feedback” process with electric fields altering the activity of the same neural elements that gave rise to them through an electrostatic mechanism. Addressing whether ephaptic coupling plays a functional role is not straightforward. Intuitively, since extracellular electric fields are always present in the living brain caused by cell functioning, it is challenging to study such functioning in the absence of the field as this would imply a comatose or deceased brain. To understand the impact of fields on neurons, a potentially more tractable question might be the following: which neural components are sensitive to extracellular fields?

As early as the 1940s, it was shown that spatially elongated neural compartments with active membrane processes and aligned within a conductive extracellular medium interact via ephaptic coupling: when inducing an action potential in one of the axons, a deflection in the membrane potential of the second axon was measured in the absence of chemical or electric synapses between the two axons (Katz and Schmitt 1940, 1942; Arvanitaki 1942). The origin of the V_m deflection in the second axon was attributed to volume conduction: the membrane currents induced by the spike along the first axon induced an extracellular field that entrained the nearby axon (Fig. 1). As expected, the features of the V_m deflection along the same axon depended on geometric considerations (distance and alignment of the axons) as well as the electric conductivity of the extracellular medium. Similar observations have been made along dendrites and somata of neurons in a number of non-physiological conditions (Nelson 1966; Dalkara et al. 1986; Turner and Richardson 1991; Anastassiou et al. 2011).

The passive cable theory dictates that the impact the field has on V_m depends on the

Local Field Potential, Ephaptic Interactions,

Fig. 1 Ephaptic coupling of the membrane potential. (a) Simultaneous recordings from two individual axons, A and B, for subthreshold (left) and suprathreshold (right) stimulation. When the stimulus into A is subthreshold, only a local response occurs. When the stimulus into A is suprathreshold, a spike propagates along A and induces a deflection in axon B. (b) Simulation of the modulation of a passive cable by an electric field. Finite cable elements sealed at both ends of variable length are subjected to a constant electric field along the cable axis. The membrane polarization (deviation of V_m from rest) is indicated on the

right as a function of cable length. (c) Spatiotemporal V_e fluctuations alter the membrane potential of neurons. Extracellular activity recorded in the behaving rat from CA1 during sharp wave activity (orientation: top, stratum oriens; bottom, stratum lacunosum-moleculare; left panel). Assume a passive neuron, i.e., no active ionic currents and no synaptic input, with realistic morphology (middle panel). The presence of endogenous V_e fluctuations entrains V_m throughout the neural morphology (Reprinted with permission from (a) Arvanitaki (1942), (b) Chan and Nicholson (1986), and (c) Anastassiou et al. (2010))

cable-field alignment as well as on three length constants: the characteristic length of the external field, the cable length, and the electrotonic length (Anastassiou et al. 2010). The range of V_m induced by a spatially inhomogeneous extracellular field can be of the order of the extracellular spatial voltage oscillation. For instance, an external sinusoidal potential profile of amplitude 0.5 mV and spatial frequency 0.5 mm aligned with a cable can give rise to V_m deviations of up to 0.625 mV. For the induced V_m amplitude to become of the order of the amplitude of V_e , two independent conditions must hold: the length of the cable must be larger than the characteristic length of the external field, and the electrotonic

length must be larger than the characteristic length of the external field. If the cable length is considerably smaller than the characteristic length of the field, the V_e gradient along the cable appears insignificant, and thus, V_m remains broadly unaltered. The same applies when the electrotonic length is much smaller than the characteristic field length: for a decreasing cable diameter (i.e., decreasing electrotonic length (Koch 1999)), the impact of the spatially inhomogeneous extracellular V_e on V_m decreases until the amplitude of the V_m deviation along the cable becomes zero. As such, for thin fibers, such as axons, the induced V_m is expected to become very small. Although these effects are derived for stationary cases,

time-dependent cases of spatially inhomogeneous V_e clearly suggest that these events persist for relatively high temporal frequencies (Fig. 2).

From the aforementioned it follows that V_m along the entire neural morphology is, to some extent, affected by the extracellular field. The specifics of such entrainment depend on the morphological and physiological features of the neuron as well as the characteristics of the extracellular field. This is especially true as active, voltage-dependent conductances are present along all neurons – spatiotemporal changes in V_e have an impact on V_m that, in turn, can also have a nonlinear impact on transmembrane conductances (Koch 1999).

Beyond V_m changes along the neural morphology, electric fields can impact the functioning of synapses. In general, a linear relationship is observed between synaptic current and V_m (with the important exception of the NMDA receptor). In fact, once the reversal potential (E_{rev}) has been accounted for, Ohm's law appears as a satisfactory first-order description of the synaptic current as $I_{syn}(t) = g_{syn}(t)(V_m(t) - E_{rev})$ with I_{syn} being the synaptic current and g_{syn} the synaptic conductance. As observed, I_{syn} depends on V_m , which, in turn, depends on V_e . Thus, changes in V_e influence synaptic currents as well. Moreover, it has been shown that both short-term (Bikson et al. 2004; Radman et al. 2009) and long-term (Fritsch et al. 2010) applications of electric fields can alter the functioning of synapses via elaborate biochemical processes. Finally, as far as an electric field can alter the spiking of neurons, correlations in spiking between two synaptically connected neurons can strongly affect the synaptic strength of their connection by inducing plasticity – this would constitute an indirect impact of ephaptic coupling on synaptic functioning (e.g., Pavlides et al. 1988; Huerta and Lisman 1995; Markram et al. 1997; Poo et al. 1998; Hoelscher et al. 1998; Hyman et al. 2002).

As ephaptic coupling impacts neural functioning at the synaptic and the single-neuron level (influencing V_m , active voltage-dependent conductances, etc.), the fact that it can also affect network-level processing should not come as a surprise (Fig. 3). Purely electrostatic, ephaptic

interaction to endogenous electric activity has been shown to play a role in neural population processing (Ghai et al. 2000; Bikson et al. 2004; Deans et al. 2007; Radman et al. 2007; Frohlich and McCormick 2010) as well as in pathological conditions such as epileptic seizures (for instance, see (Jefferys and Haas 1982); reviewed in (Faber and Korn 1989; Jefferys 1995; Weiss et al. 2013; Zhang et al. 2014)). Data supports that even weak sinusoidal extracellular stimulation during network activity may coordinate and pattern population activity by providing a common, network-wide feedback. On the other hand, *in vivo* field activity rarely exhibits a single, dominant frequency: most commonly, the power of V_e signals scales with frequency (with the exponent typically ranging between 1 and 3). As such, ephaptic feedback occurs at a spectrum of frequencies even if the effect is attenuated for higher ones. And the impact of ephaptic coupling on the network will also depend on the network state (Ozen et al. 2010). From the aforementioned it becomes clear that the functional role of ephaptic coupling of neural networks to endogenous field activity *in vivo* remains enigmatic – this is probably also due to the challenge of characterizing feedback mechanisms within inherently nonlinear networks as well as because ephaptic coupling affects processing at multiple spatiotemporal scales.

Given that extracellular fields are always part of the living, functioning brain and that *in vivo* V_e activity spans across a spectrum of frequencies (Buzsaki 2006; Buzsaki et al. 2012), it may be informative to tease apart ephaptic coupling to extracellular fields with respect to specific bandwidths. Higher V_e bandwidths are typically generated locally with the bandwidth above 500 Hz, being strongly influenced by spiking from neurons proximally located to the recording electrode (see also entry ► “Local Field Potential, Relationship to Unit Activity”). For example, extracellular spike signatures from cortical excitatory and inhibitory neurons decay within a few tens of μm from several hundred μV to zero (Henze et al. 2000; Gold et al. 2006; Anastassiou et al. (unpublished observations)). Thus, ephaptic coupling in higher bandwidths of endogenous extracellular activity is expected to depend on aspects such as local

Local Field Potential, Ephaptic Interactions, Fig. 2 (continued)

cytoarchitecture, neural activity and excitability, as well as local field characteristics (Buzsaki et al. 2012). To date, there have been two clear demonstrations of ephaptic coupling to spikes under physiological conditions: in the Mauthner cell leading to bidirectional inhibition from the Mauthner cell to its inhibitory afferents, and vice versa (Faber and Korn 1980, 1989) and in cerebellar basket cells connecting to Purkinje cells that experience a transient electric hyperpolarization following a Purkinje cell spike (Korn and Axelrad 1980). With respect to the latter, it was recently demonstrated that the pinceau, a structure where the axon initial segment of each Purkinje cell is enclosed by a basket cell, mediates ephaptic inhibition of Purkinje cell spikes at the site of spike initiation (Blot and Barbour 2014). As a result, such axoaxonic ephaptic coupling between pre- and postsynaptic neurons mediates near-instantaneous feedforward and lateral inhibition. Notably, due to the nature of the cellular membrane, ephaptic coupling to such high V_e bandwidths is expected to occur mainly via capacitive currents (Koch 1999).

Ephaptic coupling may also become important when considering the entrainment of spiking to slower extracellular fields. The V_e bandwidth below approx. 300 Hz is the so-called local field potential (LFP) which reflects synaptic, passive return but also slower active processing within the entire circuits (Buzsaki et al. 2012; Reimann et al. 2013; Einevoll et al. 2013) (see also entries

► “Local Field Potential: Relationship to Membrane Synaptic Potentials”; ► “Local Field Potential, Relationship to Unit Activity”; and ► “Current Source Density (CSD) Analysis”). It has been shown that LFP activity is spatially considerably more extended compared to the higher bandwidths of V_e . As such, ephaptic coupling to the LFP provides nearly simultaneous feedback to many neurons or even the entire networks. Computer simulations have indicated that ephaptic coupling can alter signaling characteristics within a network (Traub et al. 1985a, b), while experimental studies have suggested that even small-amplitude-slow-frequency LFP activity entrains spiking in neurons and neural assemblies (Jefferys and Haas 1982; Chan and Nicholson 1986; Chan et al. 1988; Bikson et al. 2004; Radman et al. 2007; Anastassiou et al. 2010, 2011; Frohlich and McCormick 2010; Ozen et al. 2010). Due to the nature of the cellular membrane, ephaptic coupling to the LFP, especially the slower part typically of larger amplitude, is expected to occur mainly via resistive currents (Koch 1999). Importantly, there have been reports of the extracellular medium not being purely resistive (for more details, see entry ► “Local Field Potentials: Interaction with the Extracellular Medium”). It follows from the aforementioned that a frequency-dependent impedance of the extracellular medium can result in the alteration of certain V_e characteristics in particular frequency bandwidths due to the physical properties

Local Field Potential, Ephaptic Interactions,

Fig. 2 Ephaptic coupling at the single-neuron level. (a1) Setup layout with hippocampal slice positioned between parallel plates used to impose extracellular field activity. The impact of applied sinusoidal fields on hippocampal CA3 pyramidal neurons is shown for variable (a2, a3) field strength (population statistics and for an individual neuron, respectively) and (a4) stimulation frequency. (b) Impact of the electric field on the time to first spike. Notably, the spike response changes from regular spiking to intrinsic bursting in the absence (intracellular stimulation only) versus the presence of an extracellular field. The impact of electric fields on chronaxie, i.e., the duration of stimulation pulse having twice the intensity of the threshold amplitude (rheobase), for intracellular current injection and field stimulation as a function of cell type. In all cases, a statistically significant difference between the absence and the presence of extracellular stimulation was

measured. (c) Impact of sinusoidal electric fields on spike time. Simultaneous intra- and extracellular stimulation and recordings from up to eight pipettes positioned close to the soma of a rat layer 5 pyramidal neuron. Extracellular sinusoidal stimulation is administered from one of the pipettes (red traces: average V_e) concurrently with a supra-threshold intracellular dc stimulation while V_i is monitored (green traces: V_i). While spike frequency remains unchanged in the absence vs. presence of extracellular fields (number of spikes reported; cyan, control; black, field stimulation), the spike phase (the angle of the sinusoidal stimulus at spike time) changes substantially for field strengths even below 0.1 mV/mm (stimulus frequency, 1 Hz). The increasing influence of ephaptic coupling is inferred by the increase in population vector length with field strength (Reprinted with permission from (a) Deans et al. (2007), (b) Radman et al. (2009), and (c) Anastassiou et al. (2011))

Local Field Potential, Ephaptic Interactions, Fig. 3 (continued)

or ongoing processes in that medium, which eventually may lead to frequency-dependent effects in terms of ephaptic coupling.

Even so, whether endogenous electric fields in the brain are merely an epiphenomenon of cellular functioning or whether they serve a functional role via ephaptic coupling remains a mystery. While differences on many levels are observed in the presence versus the absence of electric fields (synapses, cables, neurons, and neural populations), the overall effect is not easily assessed. Part of the difficulty has been the typically subthreshold impact: changes in membrane voltage attributed to ephaptic coupling hardly exceed fractions of a mV or a few mV. Physiologists studying, specifically, changes in membrane voltage and, more generally, input–output relationships at the single-neuron level typically deal with signals of several mV or tens of mV (in the case of intracellular spikes). The role of such subthreshold processing in neural coding is inherently challenging to decipher, especially since the nature and mode of coding and the resulting computation performed are related to many high-level functions. Also, ephaptic coupling has an intrinsically extended spatial nature: it is the spatial gradient of the extracellular voltage spanning along the extended neural morphology that gives rise to such entrainment. Accessing a number of compartments of the same neuron along the field axis to monitor ephaptic coupling is a tremendously tedious task experimentally – especially so *in vivo*. And it is infeasible to abolish

endogenous electric fields *in vivo* and perform control experiments, i.e., study neural functioning in the absence of such fields. These are some of the reasons why the role of ephaptic coupling at the neuron and, especially, the population level remains mysterious.

On the other hand, deciphering the relationship between neural functioning and electric field activity is an active area of research of fundamental importance. This relationship is not limited to biophysics – it is crucially linked to our understanding of neural processes related to behavior. For example, in monkey V4, it has been shown that spike–field coherence in gamma (30–60 Hz) is confined to superficial layers, whereas deep layers show maximal coherence around the alpha range (6–16 Hz) with attention increasing gamma synchrony in superficial layers and reducing alpha synchrony in deep layers (Buffalo et al. 2011). Many similar observations have been made over the past decades for a number of LFP bandwidths and various visual/behavioral paradigms in rodents as well as in humans (Rutishauser et al. 2010) (see also entries ► “Local Field Potential, Relationship to BOLD Signal”, and ► “Local Field Potential in the Visual System”). Clearly, to understand the mapping between neural coding, extracellular field activity, LFPs, and behavior (also) depends on whether we are in position to tease apart input and output and cause and effect. And as experimental and theoretical tools to monitor, emulate, and perturb circuit-wide processing become increasingly sophisticated, the role of

from a layer 5 pyramidal cell in somatosensory cortex. Joint probability density counts of V_i and the phase of the stimulation signal are shown for weak (0.4 V) and strong (1.2 V) intensity (red line: stimulation phase). Brain state-dependent Up–Down activity (note bimodal distribution of V_i) in the absence of an extracellular stimulus is substantially smeared during stimulus administration. (d) Percentage of significantly modulated neurons in three chronically implanted rats (a1, a2, a3) as a function of stimulation intensity. (e) Example unit histograms during transcranial stimulation. While no unit was affected by the stimulation during exploration, a fraction of cells were significantly entrained during sleep at all intensities (Reprinted with permission from (a, b) Frohlich and McCormick (2010) and (c–e) Ozen et al. (2010))

such “small” (in amplitude) mechanisms might be shown to play a more prominent role in brain function than hitherto anticipated.

Local Field Potential, Methods of Recording

Andrew Sharott

Medical Research Council Anatomical
Neuropharmacology Unit, Department of
Pharmacology, University of Oxford, Oxford, UK

Definition

The term local field potential (LFP) refers to the electrical field recorded using a small-sized electrode in the extracellular space of brain tissue that is referenced against an electrode recorded either inside or outside that tissue. Such recordings were first made in animals over 130 years ago (Caton 1875) and constitute an increasingly important tool both in neurophysiology and medicine. LFPs can be recorded using a wide variety of electrodes of varied impedance and geometry. In many experimental preparations, the primary purpose of the electrode will be to record action potentials, which are usually filtered above 500 Hz. The field potential represents the slow fluctuations, usually below 300 Hz, that are caused by all ionic process around the electrode (Buzsaki et al. 2012). Fluctuations in the LFP represent spatiotemporally synchronous events in these ionic processes, and LFPs are therefore typically used to measure large population responses to a stimulus or ongoing neuronal oscillations, both of which can cause this local summation. Unlike intracellular or action potentials from a single neuron, the LFP is not a standardized signal but will change depending on methodological details of the experimental preparation (Kajikawa and Schroeder 2011).

Detailed Description

Referencing and Filtering

The position of the reference electrode is crucial for the recording of the LFP. If the reference is distant (e.g., an epidural screw or wire in the skin), the signal is referred to as monopolar. As there is no subtraction of local activity, monopolar signals have low spatial resolution and are vulnerable to volume

conduction: transmission from a distant primary current source to the measurement sensors (Carsten and de Munck 2007). Volume conduction can therefore lead to activity from another brain area being ascribed to the area of the measurement electrode. Such contamination of the signal can be from sources up to millimeters away from the electrode (Kajikawa and Schroeder 2011). If the reference electrode is local (within a few hundred micrometers and often within the same brain structure), the signal is referred to as bipolar. Bipolar recordings can lead to the opposite problem: potentially meaningful components of the signal will be lost if they are recorded by both electrodes. Recording many LFPs, particularly in a spatially organized manner, allows referencing to be carried out offline, which may facilitate an optimal configuration between these extremes. The LFP typically consists of the signal low-pass filtered between 200 and 400 Hz. Irrespective of the configuration, filtering to extract the LFP is increasingly carried out offline on the “wideband” signal, usually sampled at >10 Hz to record action potentials and LFPs.

Recording Electrodes and Configurations

In brain slice preparations, glass electrodes with a low resistance (1–10 M Ω) can be used to record the LFP (Whittington et al. 2001). The reference electrode can be placed either locally or in another brain structure depending on the nature of the signal desired. In vitro, LFP signals have been commonly used in hippocampal slices to record network oscillations that are often induced pharmacologically (Traub et al. 2004). In vivo, a huge variety of electrodes have been used to record LFPs in anesthetized and awake animals. In anesthetized animals, signals from glass electrodes, the primary purpose of which is often to record action potentials, can be filtered to give the LFP and will usually be recorded in a monopolar configuration (Goto and O'Donnell 2001; Magill et al. 2004). In awake animals, standard microelectrodes and tetrodes are commonly used to record LFPs, with or without action potentials. Silicon probes, which have geometrically arranged electrode contacts, have several desirable qualities for recording LFPs. In particular, they

enable the calculation of current source density across laminar structures and flexible offline referencing (Buzsaki 2004). In humans, surgical interventions for epilepsy, Parkinson's disease, dystonia, and essential tremor have enabled LFP recording in the cortex, hippocampus, cerebellum, and basal ganglia (Engel et al. 2005). Such recordings have been made both using microelectrodes to map the implantation area (Weinberger et al. 2006) and using macroelectrodes implanted to deliver deep brain stimulation. Such macroelectrodes typically have four linearly spaced contacts that can be used to record monopolar (with a distant reference) or local bipolar signals (Chen et al. 2006).

Influence of Electrode Type

Despite the intuitive notion that the geometry and impedance of the recording electrode will affect the LFP signal, the issue has rarely been formally addressed (Pesaran 2009; Nelson and Pouget 2010). The issues of geometry and impedance are highly related, as the impedance is mostly a measure of the size of the uninsulated recording site (Nelson and Pouget 2010). Although the impedance of the recording electrode is crucial in determining whether intracellular or action potentials can be recorded, it has relatively little effect on the LFP signal (Nelson and Pouget 2010), at least within the limits of commonly used electrodes. One explanation for this is that the volume of tissue responsible for generating the LFP is far larger than the electrode tip (even for a large recording electrode). Larger electrodes will cause greater physical damage that is likely to affect the electrical activity of the immediate surrounding area. However, because the area generating the LFP is far bigger than the surrounding area, good signals can be recorded even using large electrodes, such as the macroelectrodes implanted for deep brain stimulation in human patients.

Influence of Recording Site and Conditions

The structural properties of the local circuit and the temporal aspects of neuronal activity within

those circuits can greatly affect the LFP signal (Niedermeyer and Lopes da Silva 2005; Buzsaki et al. 2012). The highly regular laminar arrangement of the cerebral cortex is ideal for the superposition and synchronization of dipoles and thus produces the largest LFP of all brain areas (Buzsaki et al. 2012). However, recordings in the cerebellum, which also has a highly ordered laminar structure, generate only small LFPs due to the relatively local processing in cerebellar circuits, unless abnormal population synchrony is introduced (Kandel and Buzsaki 1993; Buzsaki et al. 2012). LFPs can be recorded from the thalamus, basal ganglia, and brain stem, albeit around 1/3 smaller than those seen at the cortex, demonstrating that a strictly laminar arrangement of neuronal processes is not necessary to produce a useful LFP signal (Niedermeyer and Lopes da Silva 2005). This is likely due to these areas receiving highly synchronous input which can summate to produce ongoing fluctuations in local electrical fields. Careful consideration of these factors is therefore necessary when comparing LFPs recorded from different brain structures.

Definition

The phase-of-firing code is a neural coding scheme whereby neurons encode information

using the time at which they fire spikes within a cycle of the ongoing oscillatory pattern of network activity. This coding scheme may allow neurons to use their temporal pattern of spikes to encode information that is not encoded in their firing rate.

Detailed Description

In this entry, we define phase-of-firing coding, and we outline its properties. We first review early results that suggested the importance of temporal coding, and then we elucidate the insights concerning the central role of phase-of-firing coding in the studies of encoding of spatial variables in the hippocampus and of natural visual stimuli in primary visual and auditory cortices.

The phase-of-firing code is a temporal coding scheme that uses the timing of spikes with respect to network fluctuations to encode information about some variables of interest (such as the identity of an external sensory stimulus) that is not encoded by the firing rates of these neurons (Perkel and Bullock 1968).

Figure 1 shows a schematic representation of both a phase-of-firing code and of a firing-rate code (i.e., a code that uses only the total number of spikes fired by the neuron to transmit information). In the case of firing-rate code (top panel), two hypothetical stimuli can be distinguished from one another based on the neural response because each stimulus evokes a different number of spikes. In the case of phase-of-firing coding (bottom panel) the two hypothetical stimuli elicit neural responses which can be discriminated based on which phase (or part of the cycle) of network oscillations they are fired at, although these two hypothetical stimuli elicit similar spike counts and thus cannot be discriminated using a rate code. Thus, in a phase-of-firing code the time at which spikes are fired, measured with respect to the cycle of network oscillations, carries unique information that cannot be retrieved when ignoring the timing of spikes.

Local Field Potential, Phase Coding, Fig. 1 Schematic cartoon of firing-rate code and phase-of-firing code. In all panels, the x-axis represents peristimulus time, short vertical lines denote spike times, and each row corresponds to a different trial. Top panels show an example of firing-rate code where the two hypothetical stimuli (left, Stimulus 1; right, Stimulus 2) are encoded by the number of spikes fired by the neuron when the stimulus is presented. Bottom panels depict an example phase-of-firing code that carries

information in terms of when spikes occur within a cycle of the ongoing oscillatory network activity. Here, the network oscillation phase is divided in four sectors depending on the phase and each of them is characterized by a different color. In this example, stimulus 1 (left) and stimulus 2 (right) cannot be distinguished by the firing rate, but by their respective phases of firing compared to the underlying oscillation (green vs. red). Redrawn based on ideas presented in Panzeri et al. (2010)

Phase-of-Firing Coding in Hopfield's Analogue Pattern Recognition Model

The computational advantages of coding information by the phase-of-firing were highlighted in a classic model of analogue pattern recognition proposed by Hopfield (1995). Hopfield considered the analogue pattern recognition problem of recognizing the identity of the stimulus or of a mixture of stimuli, whatever their overall intensity. This resembles many important operations that have to be routinely performed by sensory systems, for example, the robust discrimination of the identity of an odor or of a mixture of odors independently of its intensity (Hopfield 1995). Hopfield's model incorporates a set of "encoding" neurons each representing a specific stimulus. Each encoding neuron receives a specific depolarizing input whenever the stimulus it encodes is present (for example, a particular odorant). Crucially, all the encoding neurons also receive a subthreshold oscillatory current common to all of them. In this way it is easy to produce encoding neurons that, whenever the stimulus they encode is present, fire a

spike in advance of the maximum of the intrinsic subthreshold oscillation (Fig. 2a, b). This is a form of phase-of-firing coding of stimulus identity. Under the assumption that the stimulus-specific depolarizing current received by each encoding neuron increases with the stimulus intensity, any stimulus mixture can be easily identified by a downstream neuron with a short membrane time constant (thus implementing coincidence detection) that receives the firing of the encoding neurons with a set of transmission delays. These transmission delays match the relative timing of the firing in the encoding neurons for the considered stimulus mixture to ensure that all such inputs arrive simultaneously to some of the downstream decoding neuron (Fig. 2c). A logarithmic transformation between stimulus strength and input current to the encoding neuron ensures that the times of firing in anticipation of the oscillation maximum of the encoding neurons are all rigidly shifted by the same amount if the overall strength of the stimulus mixture changes. Hopfield's model shows that encoding information by phase-of-firing

Local Field Potential, Phase Coding, Fig. 2 Illustration of Hopfield phase-of-firing model of analogue mixture coding. Panel B shows the action potentials of five different encoding neurons driven with different input current (corresponding to different analogues' signal strengths represented by the length of the black bars in Panel A). Neuron 4 produces no action potential because its input current is too weak to drive that cell above threshold. The other neurons fire just once per oscillation cycle. The time each neuron fire in advance of the maximum of the subthreshold oscillation is larger for neurons driven with a greater input current. Panel C shows a scheme to read out the phase-of-firing coding of the

stimulus mixture. The spikes generated by the encoding neurons reach out the soma of a decoding neuron at the same time because of suitably tuned differences in their conduction delays. The decoding neuron has a short membrane time constant, and thus it fires only when it receives a sufficient number of simultaneous inputs. This only happens when the appropriate analogue stimulus mixture is presented. The logarithmic dependence on each stimulus's strength of the input current to each encoding neurons insure that an overall change of intensity of the analogue stimulus mixture does not change the relative time of arrival to the encoding neuron. Panels A and B adapted from Hopfield (1995)

makes it easy to read out this information in a scale invariant way with a plausible downstream neural system.

Hopfield noted that the scale-invariant analogue matching problem is difficult to solve with a neuron using a firing-rate code. Even a "grand-mother" firing-rate neuron that is tuned only to a specific mixture of stimuli by a set of synaptic weights that boosts a specific stimulus mixture will respond to suboptimal stimulus mixtures provided that they are presented with a large enough intensity.

The phase-of-firing coding idea advanced by Hopfield coding was influential in introducing the notion that some problems that cannot easily be solved by firing-rate based schemes may be more easily solved by spike-timing based neural representations. Another influential aspect of Hopfield's phase-of-firing proposal was that it highlighted the fact that certain possible coding schemes cannot be detected when measuring spikes from single neurons only. However,

whether or not the olfactory system encodes odor information in the way proposed by Hopfield still remains to be experimentally established.

Phase-of-Firing Encoding of Spatial Navigation Variables in the Hippocampus

The activity of hippocampal neurons has long been implicated in the encoding of information of variables important for spatial navigation. In particular, so-called place cells in regions CA1 and CA3 of the rat hippocampal formation have been reported to encode the spatial location of the animal by elevating their firing when the animal is in a small spatial region called the place field of that neuron (O'Keefe 1976).

In a seminal study, O'Keefe and Recce (1993) considered how these cells encoded information. They first noted that, in contrast to the firing rate of place cells, the hippocampal field potential theta pattern of rhythmical waves (7–12 Hz) is better correlated with a class of movements that change the rat's location in an environment. In the

light of this observation, they considered the timing at which place cells fired in relation to the theta cycle. They found that firing consistently began at a particular phase as the rat entered the field but then shifted in a systematic way when traversing the field, moving progressively forward on each theta cycle. The phase-of-firing was highly correlated with spatial location and less well correlated with temporal aspects of behavior, such as the time after place-field entry. They suggested that by using the phase relationship as well as the firing rate, place cells might improve the accuracy of their place coding.

Later and more detailed studies have tried to clarify the exact nature of the information carried by the theta phase-of-firing of hippocampal cells and its relationship with the information carried by firing rates. Single-cell studies using the global statistical relationship between theta phase and spike firing could identify a partial dissociation of phase and firing rate in response to the animal's location and speed of movement (Huxter et al. 2003) but could not determine whether these signals encode complementary information about separate external features. Other studies have also shown that both theta phase and rate reflect the amplitude of the cell's input and might convey redundant spatial information (Mehta et al. 2002; Harris et al. 2002; Harris 2005). However, a population study using decoding techniques (Huxter et al. 2008) demonstrated that the phase-of-firing of hippocampal place cells encodes features related to the animal's spatial navigation that are not encoded by spike rates. Their data suggest that the best position prediction is obtained from spiking in the descending theta-cycle phase, while place cell firing on the ascending slope encodes the direction rats are heading to Huxter et al. (2008). These results imply that considering the theta phase at which hippocampal spikes are fired affords a richness of representation of information about position and heading that would not be possible with the firing-rate information only.

Note that Hafting and colleagues (2008) observed such phase-of-fire coding also in so-called grid cells of the entorhinal cortex, one synapse upstream from the hippocampus. As such

coding was not blocked by inactivation of the hippocampus, it raises the possibility that the phase-of-firing coding for hippocampal place cells is inherited from entorhinal cortex.

Phase-of-Firing Encoding of Natural Stimuli in Primary Sensory Areas

The results discussed above suggest the importance of phase-of-firing coding in the hippocampal formation. However, until recently it has been unclear whether phase coding represents a fundamental currency for cortical information exchange also in primary sensory representation and whether it is a sufficiently robust coding mechanism to represent complex stimuli.

We investigated this question by recording spiking activity and local field potentials (LFPs) from the primary visual cortex of anesthetized macaques while binocularly presenting a color movie (Montemurro et al. 2008). (LFPs are a massed measure of neural activity obtained by low pass filtering of the extracellular potential recorded with intracranial microelectrodes and capturing fluctuations in the input and intracortical processing of the local cortical network, including the overall effect of population synaptic potentials and other types of slow activity, such as spike afterpotentials and voltage-dependent membrane oscillations; see Buzsaki et al. (2012) and Einevoll et al. (2013) for recent reviews.) We found that the presentation of naturalistic color movies elicited reliable responses across trials both for the spikes and for the phase of LFPs in low frequency bands, particularly in the delta (1–4 Hz) and theta (4–8 Hz) band. However, we often found that two different movies scenes elicited very similar firing rates and thus could not be discriminated using a rate code. However, often the spikes elicited in response to scenes with similar rate were fired at a different LFP phase in each scene, thereby suggesting that the phase of firing conveyed information that could not be extracted from spike rate. We investigated this point quantitatively by computing the amount of mutual information about which movie scene was being presented that can be extracted by firing rates and by phase of firing, respectively (mutual information is a principled measure of

association between variables that is often used in neuroscience to measure the association between sensory stimuli and neural responses; see Quiroga and Panzeri (2009) for a review). The phase-of-firing was indeed found to convey information that was not accessible from the spike rates alone: the overall information about the movie increased by more than 50% when the LFP phase-of-firing was considered. The extra information available in the phase-of-firing was crucial for the disambiguation between stimuli eliciting high spike rates of similar magnitude. Thus, phase coding may allow primary cortical neurons to represent several effective stimuli in an easily decodable format.

We then investigated whether phase-of-firing coding of naturalistic information was present also in auditory cortex of awake macaques during the presentation of natural sounds input (Kayser et al. 2009). We found that also in this case, the phase-of-firing code carried information about the natural sound above and beyond that available in firing rates of auditory cortical neurons, thereby confirming the above results obtained in visual cortex. However, in auditory cortex we also found that an additional type of spike time coding scheme was at work: there were millisecond precise temporal patterns of spikes that too carried information not available in firing rates defined over longer time periods (Kayser et al. 2009). An important question was thus whether millisecond scale spike patterns carry the same or different information than the phase of slow network oscillations at which they are fired. Using again information theoretic measures, we found that information in spike rates and patterns at millisecond timescales was complementary to the information in the phase-of-firing, as sound periods not discernable from spike rates or spike patterns alone could instead be discriminated by also measuring the phase-of-firing. Together, these findings suggest that the timing of spikes measured on a millisecond scale, firing rates on a tens to hundreds of millisecond scale, and timing of spikes measured with respect to network fluctuations operating at

frequencies of a few hertz in sensory cortices constitute largely complementary information channels during naturalistic stimulation, and that these codes can be combined into highly informative codes containing “multiplexed” sensory information.

One way in which a neuron may use multiplexed codes that carry independent information at each time scale is illustrated in the simplified schematic of Fig. 3. This figure shows a cartoon of a neuron that represents information needed to discriminate odd (1 and 3) from even (2 and 4) stimuli with the fine-time scale differences of their temporal firing patterns (very small inter-spike intervals are used for stimuli 1,3 and slightly longer inter-spike intervals are used for stimulus 2,4). This example neuron represents on a much coarser time scale the information needed to discriminate stimuli 1,2 from stimuli 3,4 by using the timing of spikes with respect to the network oscillation (stimuli 1,2 are coded with spikes fired in the descending “green” part of the wave, whereas stimuli 3,4 are coded with spikes fired in the ascending “yellow” part of the wave). This example neuron thus carries all the information needed to discriminate the four stimuli only when putting together the complementary information from these two codes each operating at a different time scale.

As a caveat, it is worth mentioning that the fact that several different neural codes make a complementary contribution to the information encoded in a given brain area does not necessarily imply that all these codes make a complementary contribution to behavioral decisions based on the sensory variables represented by this neural activity. It is possible that, for example, a downstream behavioral readout mechanism is unable to access the information in some of these codes. It is thus of paramount importance that future works test the impact of different components of multiplexed codes on behavioral decisions. A complementary impact on behavior of millisecond spike patterns and firing rates has been recently reported in somatosensory cortex (Zuo et al. 2015). However, a complementary impact of phase-of-firing and

Local Field Potential, Phase Coding, Fig. 3 Schematic cartoon of a multiplexed code. In all panels, the x-axis represents peristimulus time, short vertical lines denote spike times, and waves denote the concurrent network oscillation (measured, e.g., as the Local Field Potential – LFP) recording together with the spikes, and each row corresponds to a different trial. Here, the network oscillation phase is divided in four sectors depending on the phase and each of them is characterized by a different color. In this example, stimulus 1 (left) and stimulus 2 (right) cannot be distinguished by the firing rate, but by their respective phases of firing compared to the underlying oscillation (green vs. yellow). Redrawn from Panzeri et al. (2010). Discrimination between odd (1 and 3) and even (2 and 4)

stimuli is based on fine-precision temporal spike patterns (very small inter-spike intervals are used for stimuli 1,3 and slightly longer inter-spike intervals are used for stimulus 2,4). Discrimination between stimuli 1,2 from stimuli 3,4 is based on a phase-of-firing code based on oscillations at much slower time scales than that used in the temporal spike patterns described above (stimuli 1,2 are coded with spikes fired in the descending “green” part of the wave, whereas stimuli 3,4 are coded with spikes fired in the ascending “yellow” part of the wave). In this cartoon, the example neuron thus uses multiplexing to code this stimulus set: the four stimuli can only be discriminated when putting together the complementary information from these two codes each operating at a different time scale

firing rates on behavioral decisions has yet to be reported, to our knowledge.

Finally, we also used auditory cortex recordings to investigate which kinds of sensory representations are more robust to environmental noise in the sensory input (Kayser et al. 2009). We presented naturalistic sounds either in their original form or mixed with naturalistic environmental noise, which was varied from trial to trial. Although stimulus information decreased with increasing noise for all codes, the information in the phase-of-firing with respect to slow oscillations (hence a multiplexed code) increased relative to the information in spike counts when increasing noise. This suggests that encoding information in spike times using an internal temporal reference frame, such as slow network oscillations, may be central to forming stable sensory representations in unreliable environments.

Definition

Blood oxygen level-dependent (BOLD) functional magnetic resonance imaging (fMRI) has rapidly become the leading research tool in cognitive neuroscience. Understanding how BOLD signal relates to activity of neural populations is crucial for constraining the interpretation of any fMRI in humans or animals. Here we review how the mean extracellular field potential (mEFP) recorded with extracellular electrodes samples different components of neural activity and how these components relate to the BOLD fMRI signal.

Detailed Description

In this entry, we first review the properties of the neurophysiological signals recorded with extracellular electrodes, and we then review how neurophysiological measures of neural activity related to the BOLD fMRI signal.

Extracellular Medium and Mean Extracellular Field Potential (mEFP)

The extracellular medium surrounding neurons is a volume conductor with a resistivity (specific impedance) that ranges from 200 to 400 Ωcm depending on neural site (for references, see

Logothetis 2003). This extracellular resistivity, which is higher than that of a saline bath, $\sim 65 \Omega\text{cm}$, in the frequency range of 1 Hz to 10 kHz (Logothetis et al. 2007), is mainly due to limitations on the flow of ions in the extracellular medium compared with saline. For the frequency range of electrophysiological signals (0 to about 7 kHz), inductive, magnetic, and propagative effects can be ignored, and the electric field can be considered homogeneous and purely resistive, obeying Ohm's law. In such a static description, the flow of positive ions (e.g., Na^+) into the active sites of a neuron appears as a current sink (inward current); the injected current flows down the core of the dendrites or axon. Because currents flow in closed loops, a current outflow from distant inactive membrane sites appears as a source (outward current) from which current flows back to the injection site through the extracellular medium. The finite resistance of the latter creates the extracellular field potentials (EFPs) that are measured by electrodes.

The weighted spatiotemporal sum of the sinks and sources from multiple cells is often called the mean extracellular field potential (mEFP). The weighting depends on several factors. Most importantly, the spatial alignment of elongated neural processes establishes an anisotropic conductivity across space and imparts a preferred directionality to the current flow. The directionality complicates the interpretation of the mEFP measurement: Cells whose current flow travels in opposing directions will cancel each other out. There are no practical methods for recovering information about the spatial conductance pattern because such information is rarely available, and there is no widely agreed upon model for interpreting the mEFP with respect to the factors that influence the cellular currents.

The mEFP captures at least three different types of neural activity: single-unit activity (SUA) representing the action potentials of well-isolated neurons next to the electrode tip, multiple unit activity (MUA) reflecting the spiking of small neural populations in a sphere of 100–300 μm radius, and perisynaptic activity of a neural population within 0.5–3 mm of the electrode tip, which is reflected in the variation of the low-

frequency components of the EFP (this is the so-called local field potential – LFP). MUA and LFP can be reliably segregated by frequency band separation. A high-pass filter cutoff of 800–1000 Hz is used in most recordings to obtain the MUA and a low-pass filter cutoff of ca. 500 Hz to obtain LFP. A large number of experiments have presented data indicating that such a band separation does indeed underlie different neural events. In the following we examine the properties of SUA, MUA, and LFP.

Single-Unit Activity (SUA) Recordings

If a microelectrode with a small tip is placed close to the soma or axon of a neuron, then the measured mEFP directly reports the spike traffic of that neuron and frequently that of its immediate neighbors as well. Single-unit spike times are typically obtained by first thresholding the high-frequency part of the mEFP (above approximately 700–800 Hz) to identify spiking events and then by using clustering techniques to sort spikes from different individual neurons.

The firing rate of such well-isolated neurons has been the critical measure for comparing neural activity to sensory processing or behavior ever since the early development of microelectrodes (Adrian and Zotterman 1926), and it has been the mainstay of systems neuroscience for decades.

A great deal has been learned since then, and the single-electrode single-unit recording technique still remains the method of choice in many behavioral experiments with conscious animals. However, it also has the drawback of providing information mainly on single receptive fields, with no access to subthreshold integrative processes or the associational operations taking place at a given site. Moreover, it suffers from an element of bias toward certain cell types (cf. (Stone 1973) and sizes (Towe and Harding 1970). The size bias, which is partially responsible for the cell-type bias as well, is considerable. For equivalent transmembrane action potentials, the discharge of a large neuron generates a substantially greater flow of membrane current and a larger extracellular spike than a small cell, and the

resulting extracellular field remains above recording noise levels over a greater distance. Larger neurons (cells with 20–30 μm diameter or greater) are estimated to generate a potential of 100 μV or more within a 100 μm -diameter sphere with the electrode tip at its center (Rall 1962). The amplitude of this potential decreases rapidly with increasing distance from the electrode tip because of the aforementioned low-pass properties of the extracellular medium. Spikes generated by large neurons will thus remain above the noise level over a greater distance from the cell than spikes from small neurons, so microelectrodes are likely to sample their somas or axons preferentially, a prediction supported by experimental work (Towe and Harding 1970; Humphrey and Corrie 1978). It follows that the measured spikes may actually represent only very small neural populations of large cells, which in cortex are by and large the principal cells (e.g., pyramidal cells in cerebral cortex and Purkinje neurons in cerebellar cortex). Recording from interneurons (e.g., inhibitory cells) is often very difficult both because of their size and because their response is often found to be uncorrelated to the stimulus or behavior state of the animal.

In conclusion, the vast majority of experiments employing single-unit extracellular recordings report on the activity of large principal cells, which represent the output of the cortical area under study. It is the firing rate of these principal neurons that is commonly used to compare the results of animal and human studies.

Multiunit Spiking Activity (MUA)

MUA can be estimated in two ways. The first is estimated by identifying individual spikes by thresholding the high-pass signal (sometimes with the additional step of convolving the resulting spike time series with a temporal kernel), without the additional step of trying to sort and cluster single units. The second is estimated by first high-pass filtering the EFP in the range of more than ~ 700 –800 Hz and then rectifying it. The former method is more suited to sample activity of few neurons, and the latter method is

more suited to sample spiking activity in a larger area of diameter of few hundred microns around the electrode.

The magnitude of EFPs in the high-frequency MUA range was shown to be a function of cell and axon size. Combined physiology-histology experiments demonstrated that the magnitude of MUA is site specific (Buchwald and Grover 1970) and thus also cell-size specific (Nelson 1966), varying considerably from one brain region to another but remaining relatively constant for any particular site (e.g., neocortex vs. hippocampus). Homogeneous populations of large cells were found to systematically occur at sites of large-amplitude fast activity, and vice versa (Grover and Buchwald 1970). Similarly, the magnitude of axonal spikes is directly correlated with the size of the transmitting axon (Gasser and Grundfest 1939; Hunt 1951). All of these experiments show that MUA-range activity reflects the variations in the magnitude of extracellular spike potentials. In other words, large-amplitude signal variations in the MUA range reflect large-amplitude extracellular potentials, and small-amplitude fast activity is correlated with small ones.

The summation range for the fast MUA has also been studied by a number of investigators. Electrodes with exposed tips of approximately 100 μm (impedance from 40 to 120 $\text{k}\Omega$), for example, were estimated to record from a sphere with a radius of 50–350 μm (Grover and Buchwald, Legatt et al. 1980), whereby the activity from each point within the sphere is weighted by a factor depending on the distance of the point from the tip of the electrode (Nicholson and Llinas 1971). Recent tetrode recordings suggest that it is possible to sample individual spikes up to a distance of approximately 140 μm from the electrode tip (Henze et al. 2000). Given the estimated number of neurons contained in a cylindrical region with 140 μm diameter in the hippocampal area CA1 (Boss et al. 1985; Aika et al. 1994), single-electrode recordings could provide information concerning the activity of approximately 1000 neurons (Henze et al. 2000). In the primary visual cortex, which contains about 200,000 neurons beneath 1 mm^2 of cortical surface (Powell and Hendrickson 1981; O’Kusky and Colonnier

1982), this number is likely to be considerably higher.

All in all, depending on the recording site and the electrode properties, the MUA most likely represents a weighted sum of the extracellular action potentials of all neurons within a sphere of approximately 140–300 μm radius, with the electrode at its center. Spikes produced by the synchronous firings of many cells can, in principle, be enhanced by summation and thus detected over a larger distance (Huang and Buchwald 1977; Arezzo et al. 1979).

Local Field Potential (LFP)

The LFP is the low-frequency range of the mEFP signal and is typically computed by low-pass filtering the mEFP below 500 Hz. LFPs represent mostly slow events reflecting cooperative activity in neural populations. Until recently these signals were thought to represent exclusively synaptic events. Evidence for this came from combined electroencephalographic (EEG) and intracortical recordings showing that the slow wave activity in the EEG is largely independent of neuronal spiking (Ajmone-Marsan 1965; Buchwald et al. 1965; Fromm and Bond 1967). These studies showed that, unlike the multiunit activity, the magnitude of the slow field fluctuations is not correlated with cell size, but instead reflects the extent and geometry of dendrites in each recording site. Cells in the so-called open field geometrical arrangement, in which dendrites face in one direction and somata in another, produce strong dendrite-to-soma dipoles when they are activated by synchronous synaptic input. Other cortical neurons are oriented horizontally and contribute less efficiently or not at all to the sum of potentials. The pyramidal cells with their apical dendrites running parallel to each other and perpendicular to the pial surface form an ideal open field arrangement and contribute maximally to both the EEG and LFP.

Evidence concerning the origin of LFPs can also be gathered from current-source density (CSD) analysis and combined field potential and intracellular recordings (for a review of CSD as

well as other types of ensemble recordings, see Mitzdorf 1985, and Nadasdy et al. 1998). Mitzdorf has suggested that LFPs actually reflect a weighted average of synchronized dendrosomatic components of the synaptic signals of a neural population within 0.5–3 mm of the electrode tip (Mitzdorf 1987; Juergens et al. 1999). The upper limits of the spatial extent of LFP summation were indirectly calculated by computing the phase coherence of LFPs as a function of interelectrode distance in experiments with simultaneous multiple-electrode recordings (Juergens et al. 1996) and were also investigated in realistic simulations of networks of multicompartmental neurons that computed the radius around the electrode containing the neural sources that provide most of the LFP amplitude (Linden et al. 2011).

LFPs were initially attributed exclusively to population excitatory or inhibitory postsynaptic potentials that are considerably slower than the spiking activity. Later studies, however, provided evidence of the existence of other types of slow activity unrelated to synaptic events, including voltage-dependent membrane oscillations (Kamondi et al. 1998) and spike afterpotentials. To be more specific, the soma-dendritic spikes in the neurons of the central nervous system are generally followed by afterpotentials, a brief delayed depolarization, the afterdepolarization, and a longer lasting afterhyperpolarization, which are thought to play an important role in the control of excitation-to-frequency transduction (Granit et al. 1963; Harada and Takahashi 1983; Gustafsson 1984). Afterpotentials, which were shown to be generated by calcium-activated potassium currents (Harada and Takahashi 1983; Fulton and Walton 1986; Higashi et al. 1993; Chandler et al. 1994; Kobayashi et al. 1997), have a duration on the order of tens of milliseconds and most likely contribute to the generation of the LFP signals (Buzsaki et al. 1988).

Because multiple neuronal processes contribute to the LFP, the signal is inherently ambiguous and more difficult to interpret than spikes. This ambiguity can, at least in part, be resolved by using computational analysis and modeling to disambiguate the different neural contributions to the LFP (Einevoll et al. 2013).

The simplest, and most traditional, way to separate different contribution to the LFP is to use the frequency domain. Low-frequency signal modulations are classified in a number of specific frequency bands initially introduced in the EEG literature (see, e.g., Elul 1969, and Pedley and Traub 1990). Rhythmic EEG is subdivided into frequency bands known as delta (0–4 Hz), theta (4–8 Hz), alpha (8–12 Hz), beta (12–24 Hz), and gamma (40–100 Hz) that are typically characterized by different amplitudes (Lindsley and Wicke 1974; Steriade and Hobson 1976; Basar 1980; Steriade 1991). The validity of this approach is supported by the strong correlation of each band with a distinct behavioral state, by the largely independent modulation of these bands with sensory inputs (Belitski et al. 2008), and by evidence suggesting that each band is generated by partly different mechanisms. For example, the oscillatory activity in the delta, theta, and alpha bands is associated with the thalamocortical loops and is modulated by the ascending network system and basal forebrain (Steriade 1991; Steriade et al. 1993), while the oscillatory activity in the gamma range is associated with the rhythmic interplay of local inhibition and excitation (Fries et al. 2007). Although the definition of the exact frequency boundaries of each band is often largely arbitrary and based on heuristic criteria that vary substantially between studies, these boundaries can be also determined by rigorous procedures that minimize the overlap both in terms of signal and of noise correlations across different bands (Magri et al. 2012a).

In summary, LFP signals and their different band-limited components (alpha, beta, gamma, etc.) are invaluable help for understanding cortical processing, as they are the only signs of integrative processes in excitation-inhibition networks. In fact, LFP do not, as initially thought, solely reflect population postsynaptic potentials, but also integrative soma-dendritic processes – including voltage-dependent membrane oscillations and afterpotentials following soma-dendritic spikes – that all together represent the local (perisynaptic) activity in a region.

Summary of Components of mEFP

MUA mostly represents the spiking of neurons, with single-unit recordings mainly reporting on the activity of the projection neurons that form the exclusive output of a cortical area. LFPs, on the other hand, represent slow waveforms, including synaptic potentials, afterpotentials of somato-dendritic spikes, and voltage-gated membrane oscillations, that reflect the input of a given cortical areas as well as its local intracortical processing, including the activity of excitatory and inhibitory interneurons. Given the complementarity of these signals, it is apparent that the most useful information will not be derived by one type of signal alone, but rather by the study of relative changes in one signal or the other. Electrophysiological studies examining the individual contributions of different LFP frequency bands, multiple unit activity, and spiking of individual neurons are probably our only realistic chance of gaining insights into the neural mechanisms of hemodynamic responses and their meaning in the context of different cognitive tasks.

Relationship of mEFP to the BOLD fMRI Signal

The relationship of neocortical LFPs and spiking activity to the BOLD signal itself was examined directly in concurrent electrophysiology and fMRI experiments in the visual system of anesthetized (Logothetis et al. 2001) and alert (Goense and Logothetis 2008) monkeys. These studies found that the BOLD responses reflect input and intracortical processing rather than pyramidal cell output activity. At first glance, both LFPs and spiking seemed to be correlated with the BOLD response. However, quantitative analysis indicated that LFPs are significantly better predictors of the BOLD response than multiunit or single-unit spiking. For example, the band-limited power of the gamma band of the LFP carries twice more information about future values of the BOLD than the MUA power does (Magri et al. 2012b).

The decisive finding leading to the conclusion that BOLD responses reflect input and

intracortical processing rather than pyramidal cell output activity, however, is not the degree of correlation between the neural and the fMRI responses or the differential contribution of any type of signal into the BOLD responses (Goense and Logothetis 2008), but rather the striking, undiminished hemodynamic responses in cases where spiking is entirely absent despite a clear and strong stimulus-induced modulation of the field potentials (Logothetis et al. 2001; Goense and Logothetis 2008). Similar dissociations between spikes and cerebral blood flow (CBF) had been demonstrated in a number of studies using other techniques (Mathiesen et al. 1998; Viswanathan and Freeman 2007; Rauch et al. 2008).

The findings are also in close agreement with a number of older autoradiography studies, also showing that regional glucose utilization is directly related to neuronal synaptic activity (Jueptner and Weiller 1995). For example, the greatest uptake of 2- ^{14}C 2 deoxyglucose (an indication of glucose consumption and thus of metabolism) occurs in the neuropil, i.e., in areas rich in synapses, dendrites, and axons, rather than in cell bodies. During orthodromic and antidromic electrical microstimulation, only the first, which involves presynaptic terminals, increases glucose consumption. Similarly, the highest density of cytochrome oxidase (an enzyme of the respiratory chain) is found in somato-dendritic regions that are adjacent to axon terminals. Last but not least, as mentioned earlier, presynaptic activity increases metabolism even when the output is inhibited, i.e., the spiking activity is abolished.

The correlation between BOLD and LFP is strongly frequency dependent. The LFP gamma frequency band carries almost twice more information about the BOLD than any other frequency component of the mEFP (Magri et al. 2012b). Both increases and decreases in BOLD signal follow increases and decreases in LFP gamma power. The reasons of the frequency dependence of the LFP-BOLD relationship are still unknown, although phenomenological models have been proposed (Kilner et al. 2005). Understanding the nature of this relationship is potentially important because it may allow a partial identification of

contributions of different neural pathways to cortical processing using fMRI.

Despite all the above evidence, some discussion still concentrates on the importance of the firing rate of action potentials of projection neurons in the generation of the hemodynamic responses, perhaps stemming from the fact that important early studies of neural correlates of behavior took the mean spiking rate to be the gold standard for quantifying neuronal activation. These discussions, however, often suffer from a certain amount of contention-seeking where none is warranted. In many cases, spikes do indeed correlate with LFPs, and they will also correlate with BOLD. In addition, unusually high correlations between MUA and BOLD (or LFP and MUA) typically reflect excessive averaging due to long image repetition times, i.e., sampling rates of several seconds rather than a fraction of a second (for a detailed discussion, see Goense and Logothetis (2008)).

Can We Predict Neural Activity from the fMRI Signals?

fMRI signals are presumed to result from changes in the activity of the neuronal populations responsible for the functions in question. The psychologist or cognitive neuroscientist who finds a cortical area to be activated by the task at hand implicitly or explicitly assumes an increase in the spiking rate of specialized neurons underlying the subject's behavior. This might well be true in some cases, but not in all. When attempting to interpret the fMRI signal by modeling or when comparing the results of human neuroimaging to those obtained in monkey physiology experiments, it is useful to take the following facts into consideration.

In humans, there are about 100,000 neurons under 1 mm² of cortical surface. This number is relatively constant for all structurally and functionally distinct areas, including the somatosensory, temporal, parietal, frontal, and motor cortical areas (Rockel et al. 1980; Braitenberg and Schuez 1998). An exception is the primary visual cortex of certain primates, including monkey and man,

which has approximately twice as many neurons. The number of neurons is also similar across many species, including mouse, rat, cat, monkey, and human. Neural density is 20,000–30,000 neurons/mm³ (Cragg 1975; Rockel et al. 1980), and synaptic density ranges from 0.4 to 1×10^9 /mm³. It follows that the average voxel size, often about 55 μ L size, contains 5.5 million neurons, $2.2\text{--}5.5 \times 10^{10}$ synapses, 22 km of dendrites, and 220 km of axons! This “large population view” is in sharp contrast to the scope of the traditional microelectrode recordings. In addition, there exists a strong selection bias during extracellular recordings, which is partly due to practical limitations, e.g., injury or simply size bias (Logothetis and Wandell 2004), and partly to the physiological properties of neurons and/or the organizational principles of neural networks. In fact, many different types of electrical and optical measurements provide evidence that a substantial proportion of neurons, including the cortical pyramidal cells, might be silent (Shoham et al. 2006). Their silence might reflect unusually high input selectivity or the existence of decoding schemes relying on infrequent co-spiking of neuronal subsets. Most important for the comparison of neuroimaging and electrophysiology results is the fact that lack of measurable neuronal spiking may not necessarily imply lack of input and subthreshold processing.

A direct analogy between neuronal spiking as measured in animal experiment and the fMRI signal obtained in human recording is thus simply unrealistic and might often lead to wrong conclusions. It is hardly surprising that most studies so far relying purely on BOLD fMRI failed to reveal the actual neural properties of the studied area, at least those properties, e.g., selectivity to various visual features that were previously established in electrophysiological studies. The fMRI signal cannot differentiate between function-specific processing and neuromodulation and between bottom-up and top-down signals, and it may potentially confuse excitation and inhibition. In cortical regions in which stimulus- or task-related perceptual or cognitive capacities are sparsely represented, e.g., instantiated in the activity of a very small number of neurons, volume

transmission which probably underlies the altered states of motivation, attention, learning, and memory may dominate hemodynamic responses and make it impossible to deduce the exact role of the area in the task at hand.

Local Field Potential, Relationship to Electroencephalogram (EEG) and Magnetoencephalogram (MEG)

Stephanie R. Jones

Department of Neuroscience, Brown University, Providence, RI, USA

Definition

Electrical currents produced by neural circuits in the brain create both electric fields and magnetic fields. The electrical field activity can be measured close to the neural source with intracranial extracellular microelectrodes and is referred to as the local field potential (LFP). The electric and magnetic fields can also be measured extracranially at a distance from the source on the surface of the head with electroencephalography (EEG) and magnetoencephalography (MEG), respectively.

Detailed Description

Recordings of Different Scales

The LFP is considered a microscopic scale measurement, while MEG and EEG are considered macroscopic scale measurements. A main distinction in microscopic versus macroscopic scale activity is the volume of neural space contributing to the recorded signals and the conductivity profile assumed to impact the measurement, discussed below.

Measurement Devices

Electrical fields in the brain are large enough that they can be measured intracranially with microelectrodes for LFPs and extracranially with macroelectrodes on the scalp for EEG (Buzsaki et al. 2012). Magnetic fields are comparably very small, on the order of $10\text{--}10^3$ femto-Tesla (fT),

but can be measured extracranially with ultra-sensitive detectors known as superconducting quantum interferences devices (SQUIDS) (Fig. 1). MEG devices house the SQUIDS in a dewar that is filled with helium to keep the SQUIDS at superconducting temperatures and MEG is enclosed in a magnetically shielded room to block extraneous magnetic fields in the environment, on the order of 10^8 fT (Hamalainen et al. 1993).

Equations Regulating Relationship Between Electric and Magnetic Fields: The Forward Solution

Given an electrical current in the brain that changes relatively slowly (e.g., <100 Hz), the electric (E) and magnetic fields (B) it produces can be calculated from the quasistatic approximation of Maxwell's Equations:

$$\begin{aligned}\bar{\nabla} \cdot E &= \frac{\rho}{\epsilon} \\ \nabla \times E &= 0 \\ \nabla \cdot B &= 0 \\ \nabla \times B &= \mu_0\end{aligned}$$

and $\nabla \cdot J = 0$ (conservation of current), where ϵ is the permittivity of the medium, ρ is the charge density, μ_0 is the permeability of free space, and J is the electric current density due to free charges.

The total current density J can be split into two components: the primary current, J^p , which represents the neural current that generates the electric and magnetic fields (see red arrows in Fig. 1), and the extracellular volume or return current, J^v (shown in green in Fig. 1), which is proportional to the conductivity, σ , and the electric field, $J^v = \sigma E$. Thus, the primary current can be represented as

$$J^p = J - \sigma E$$

Since $\nabla \times E = 0$, the electric field can be expressed with a scalar potential, $E = -\nabla V$.

Taking the divergence (bi-domain approximation), we obtain

Local Field Potential, Relationship to Electroencephalogram (EEG) and Magnetoencephalogram (MEG), Fig. 1 Schematic illustration of the relationship between microscopic local field potentials (LFPs) measured intracranially with microelectrodes and macroscopic electric and magnetic fields measured extracranially with electroencephalography (EEG) and magnetoencephalography

(MEG), respectively. In the neocortex, the primary electrical current sources (J^P) underlying extracranially measured electric (V) and magnetic fields (B), and contributing to local extracellular electric fields (volume currents, J^V), are thought to be generated mainly by the net postsynaptic intracellular current flow in the long and spatially aligned dendrites of pyramidal neurons

$$\begin{aligned}\nabla \cdot J^P &= \nabla \cdot (J - \sigma E) = \nabla \cdot J - \nabla \cdot \sigma E \\ &= \nabla \cdot (\sigma \nabla V)\end{aligned}$$

and arrive at a Poisson Equation for the electric potential

$$\nabla \cdot (\sigma \nabla V) = \nabla \cdot J^P$$

With the proper boundary conditions, and knowledge of σ and J^P , this equation can be solved for V with finite element techniques. Once V is known, the magnetic field, B (blue in Fig. 1), can be computed from Biot-Savart law

$$B(r) = \frac{\mu_0}{4\pi} \int_G J^P(r') \times \frac{R}{R^3} dV$$

where the integration is performed over a volume G containing all active sources and $R = r - r'$ is a vector connecting the location of the source r' to point r where the magnetic field is computed. In an infinite homogeneous volume conduction, the volume currents give no contribution to the electric potential or magnetic field (see (Hamalainen et al. 1993) for derivation). If we assume the volume at which the current flow consists of

homogeneous compartments, both the electric potential and magnetic field can be computed from integral equations involving the value of V on the boundary surface with boundary-element methods (BEM) (Hamalainen and Sarvas 1989).

Further, in a spherical head model, the MEG signals can be calculated directly from the primary current without explicit reference to the structure of the conductor (unlike LFP or EEG). Additionally, radial currents do not produce a magnetic field outside of a spherical conductor model. In contrast, EEG will record fields produced by both radial and tangential current sources, shown in the gyri and sulci, respectively, in Fig. 1. This difference makes the inverse problem easier for MEG than EEG.

While the primary current, J^P , creating the LFP, MEG, and EEG signals can be in principle equivalent, the distance from the current sources over which the electric or magnetic field is calculated necessitates vastly different assumptions on the conductivity profile, σ , and the neural interpretation of the signal can be very different.

LFP: When calculating the forward solution for LFP, a homogeneous extracellular medium is

typically considered with a constant isotropic conductivity profile (Linden et al. 2011). More complicated anisotropic conductivity gradients have been considered (Bedard et al. 2004; Bedard and Destexhe 2009; Anastassiou et al. 2010) and are particularly important for higher frequency signals.

EEG/MEG: When calculating the forward solution for EEG/MEG, a macroscopic scalar measure of conductivity σ with at least 1-mm scale is assumed, and head models with realistic conductor geometries can be determined with structural MRI. For MEG a highly accurate solution can be obtained with BEM by considering only one homogeneous compartment bounded by the inner skull; for EEG at least 3 compartments need to be considered, the scalp, skull, and brain (Hamalainen and Sarvas 1989).

Determining the Current Sources: The Inverse Problem

Estimating the location and temporal evolution of the primary current sources producing the recorded electric or magnetic fields is a problem termed the inverse problem. Inferring the underlying neural level events that create these primary currents is an additional challenge.

LFP: By definition, LFPs are presumed to be local to the current source generators. However, interpreting the exact spatial reach of the recorded activity and the neural level generation is complex and depends on many things including the local cell types, their active membrane properties and morphologies, synaptic arrangements, and the level of neural synchrony (Linden et al. 2011; Reimann et al. 2013). It is generally assumed that low-frequency LFP (<100 Hz) emerges mainly from slower transmembrane postsynaptic events but the geometry of the cells, as well as other non-synaptic events, including glial activity, can greatly influence the extracellular field (Buzsaki et al. 2012). In the neocortex, the synapses on spatially aligned and parallel

orientated pyramidal neuron (PN) dendrites have been hypothesized to dominate the LFP signal, and there is often an agreement between LFP signals and surface EEG signals due to their prominent impact on the extracellular field (Linden et al. 2011; Buzsaki et al. 2012).

EEG/MEG: Estimating the primary current source densities underlying macroscopically measured EEG or MEG signals is an inherently ill-posed problem because the inverse solutions are nonunique (e.g., different spatial-temporal distributions of current sources can give the same forward solution). Additional physiological constraints are used to constrain the problem and simplify the forward solution, including replacement of the actually primary current sources by equivalent generators or point sources referred to as current dipoles, and the assumption that these primary current dipoles are restricted to the cortical surface, which can be accurately modeled with structural MRI. Once a forward solution is determined, a unique solution to the inverse problem can be found by comparing to the recorded data (e.g., least squared fit). There are many alternative approaches to accurately estimate the sources contributing to EEG/MEG measurements, including multi-dipole models and current distribution models, reviewed in Hamalainen et al. (1993).

The neural source of the primary currents estimated with EEG/MEG inverse methods is commonly thought to be the summed postsynaptic longitudinal currents flowing inside the dendrites of the large spatially aligned cortical PNs in a direction perpendicular to the cortical surface (Hamalainen et al. 1993; Okada et al. 1997; Ikeda et al. 2005); see red arrow in Fig. 1. Due to the long length of the deep Layer V PNs apical dendrites, they are thought to dominate the recorded activity (Murakami and Okada 2006; Lee and Jones 2013). The more neurons that participate in synchrony, the bigger the signal will be. Estimates on the size of cortical volume that creates a minimally measurable primary current signal (~ 10 nano-Ampere-meter) are $\sim 10^6$ PNs (Jones et al. 2007).

Computational Modeling

From a computational modeling standpoint, modeling the macroscopic primary current source signals estimated with inverse methods from MEG/EEG with intracellular PN dendritic current flow in multi-compartment neurons, as in Murakami et al. (2002, 2003), Murakami and Okada (2006), Jones et al. (2007, 2009), Ziegler et al. (2010), and Lee and Jones (2013), can be a more tractable problem than modeling the microscopic extracellular LFP or macroscopic EEG signals at the sensors level (i.e., the forward solution). Models of LFP signals need to account for greater details of the local network and extracellular conductivity gradients (Bedard et al. 2004; Bedard and Destexhe 2009; Anastassiou et al. 2010; Linden et al. 2011; Reimann et al. 2013). Models of EEG sensor activity calculated with forward models need to account for folding in the cortical surface and conductivity profiles of the brain tissue, spinal fluid, and skull (Barres et al. 2013). Constructed with proper biophysics, computational neural models can serve as the interpretive link between the different scales of activity.

Synonyms

Contamination by spikes; Electroencephalogram; Local field potential; Relation to unit activity; Spike contribution; Spike-triggered average

Definition

Unit activity usually refers to timing of spikes elicited by individual neurons (single unit activity, SUA) or local ($r < 140 \mu\text{m}$) population of neurons (multi-unit activity, MUA; Buzsáki 2004). Although local field potential (LFP) reflects both subthreshold and spiking activities that are summed over larger population of neurons ($r < 450 \mu\text{m}$, Berens et al. 2008), usually it does not display discriminable spikes. Nevertheless, the amplitude of high-frequency LFP ($>40 \text{ Hz}$) often correlates with population firing rate,

whereas the phase and amplitude of low-frequency LFP ($<10 \text{ Hz}$) modulates this relationship. The LFP-spike relation is very sensitive to neuronal correlations – at high synchrony levels neurons produce macroscopic spikes visible in the raw LFP signal (“population spikes”).

Detailed Description

The basic physical phenomena involved in generation of LFP are common across all types of neuronal activities, including unit activity (spikes). However, there are several factors that differentiate unit contributions from, for example, synaptic contributions: (1) Their spatial locality leads to rapid decay of their contribution with distance; (2) their short duration hinders the summation of contributions from multiple units; (3) their high-frequency power is cut off by biological medium and hardware filters.

Despite these difficulties some experimental paradigms unveil a substantial spike-related component in the low- and high-frequency LFP signals.

Spike Correlates in High-Frequency LFP ($>40 \text{ Hz}$)

In cat visual cortex, presentation of light bars evokes oscillations at frequencies 35–50 Hz that are tightly correlated with spikes in local neuronal population (MUA; Gray and Singer 1989). These gamma-band oscillations most likely reflect synchronous activation of larger population of cells.

Coupling between LFP and spikes is even stronger at frequencies above 60 Hz: as demonstrated by experiments in visual cortex the power of stimulus-induced high-gamma LFP (60–200 Hz) closely follows the concomitant increase in population firing rate (Ray et al. 2008; Burns et al. 2010). Similar relationship between spontaneous LFP and MUA is also observed in ongoing activity (Destexhe et al. 1999).

Owing to its fine temporal resolution, high-frequency LFP allows to discriminate the timings

Local Field Potential, Relationship to Unit Activity, Fig. 1 Relation of LFP to unit activity in monkeys and cats. **(a)** High-frequency EEG waveforms covary with temporal spike patterns of single units in somatosensory cortex of macaques. Neurons respond to identical stimulation with variable bursts of spikes (top panel: average post-stimulus time histogram in gray, dotted lines – intraburst intervals), which can be classified into one of a few stereotypical spike patterns (raster plot: sample spike trains of two of such patterns). Peaks of high-frequency EEG align to the preferred “spike windows” and their amplitude depends on the spike pattern of simultaneously recorded unit (bottom: average EEG traces coincident with a spike pattern plotted in same color; *significant difference,

$p < 0.05$). (Modified from Telenczuk et al. (2011)). **(b)** LFP-spike correlation depends on the brain state. Spike-triggered LFP average (LFP-STA) calculated in awake state (top) and REM sleep (middle) of cats are shorter in time and smaller in amplitude compared to the slow-wave sleep LFP-STA (SWS, bottom). In all three states randomly shuffling spikes with respect to LFP eliminated the correlations (thin lines below each LFP-STA). **(c)** LFP reflects unit activity that is locally correlated with respect to fast oscillations and globally correlated with respect to slow oscillations. Schematic representation of synchrony of nearby and distant units in relation to troughs of slow (top) and fast oscillations (bottom). **(b)** and **(c)** were modified from Destexhe et al. (1999)

of spikes. When multiple neurons become tightly synchronized, they elicit coincident spikes, which jointly produce discriminable peaks in field potentials (LFP or EEG) even at distant locations (“population spikes,” Andersen et al. 1971). This mechanism, for instance, is involved in generation of macroscopic high-frequency (>200 Hz) bursts in somatosensory cortices of nonhuman primates (Fig. 1a; Baker et al. 2003), rodents (Jones et al. 2000), and frequency-following neurophonic potentials in auditory system of barn owls (Kuokkanen et al. 2010).

Since MUA and LFP are often recorded with the same electrodes, spike waveforms of nearby units may contaminate the LFP, exaggerating the observed correlations. Indeed, low-frequency

band of extracellularly recorded spikes overlaps with gamma/high-gamma band of LFP. However, the subtraction of spike waveforms from LFP affects mainly frequencies above 100 Hz (Belluscio et al. 2012) decreasing but not completely eliminating the correlation between spikes and high-gamma LFP (Zanos et al. 2011).

Relationship Between Low-Frequency LFP (<10 Hz) and Unit Activity

Often the population firing rate may be inferred from the LFP alone, but only when both its low- and high-frequency bands are considered. The most informative features are high-gamma

power (40–90 Hz), and the phase and amplitude of low-frequency oscillations (<10 Hz; Rasch et al. 2008).

Low- and high-frequency LFP bands are inter-related: When awake monkeys are presented with natural movies, the correlation between MUA and gamma-band EEG (which shares many features with LFP) is the highest in the troughs of delta oscillations (2–4 Hz; Whittingstall and Logothetis 2009).

LFP signals in the intermediate frequency bands between 10 and 40 Hz are not clearly related to unit activity (Rasch et al. 2008; Belitski et al. 2008).

Mechanisms of Spike Contribution to LFP

The sources of correlations between LFP and unit-activity are very diverse and it is impossible to single out any particular cause except in few specific scenarios. Nevertheless, two main mechanisms underlie most of the phenomena listed above: (1) contribution through synchronous synaptic release triggered by a spike arriving at axon terminals; (2) direct contribution of ionic currents underlying the spike.

A spike of a single neuron triggers a large number of synaptic potentials in its post-synaptic targets. Despite their small amplitude, post-synaptic potentials can produce large extracellular field (“unitary field potential”) provided that they are spatially and temporally clustered. This occurs at synapses formed by hippocampal interneurons (area CA3), whose spikes generate an LFP bump at monosynaptic latency (Bazelon et al. 2010). It was shown from human and monkey microelectrode recordings that the main spike contribution to LFPs is inhibitory (Telenczuk et al. 2017a), which was recently confirmed by computational models (Telenczuk et al. 2020a). Such features can be used to design methods to calculate LFPs from networks of spiking neurons (Telenczuk et al. 2020b).

The relationship between spikes and LFPs can also be seen in cases where the spiking activity is very tightly timed. For example, fast,

synchronous post-synaptic potentials may underlie bursts of high-frequency LFP oscillations in vivo (Fig. 1a, Telenczuk et al. 2011, 2017b).

Action potentials initiate and propagate due to an interplay between a variety of membrane currents. Axon currents that are involved in propagation of action potentials produce only slight extracellular fields except at both axon ends or while crossing volume conductor boundaries (Jewett et al. 1990). However, action potentials activate also sodium currents in soma and calcium currents in the dendrites, which, in turn, may generate strong contribution to field potentials especially at high frequencies (Murakami et al. 2003). In contrast, slow potassium currents, which hyperpolarize membrane after a spike, can contribute significantly to low-frequency LFP; for example, a slow potassium current shapes the wave component of so-called spike-and-wave complex (Destexhe 1998). Since the extracellular medium is more conductive at low frequencies, it favors these slow currents over faster sodium spikes (Bédard et al. 2004).

Rather than contributing directly to LFP, active ion channels may also modulate low-frequency LFP by shunting synaptic currents (Reimann et al. 2013).

Recent evidence for monopolar effects in LFP generation (Riera et al. 2012) has triggered a discussion about possible physical mechanisms for neuronal monopoles (Destexhe and Bedard 2012; Bedard and Destexhe 2013; Gratiy et al. 2013). If confirmed, such monopolar effects should have strong consequences on the genesis of LFP, even if they occur transiently (Destexhe and Bedard 2012). This possible monopolar contribution should be clarified by future theoretical and experimental studies.

The correlation between low-frequency LFP and unit activity is not always causal, sometimes it results from a common source of variations, such as global changes in the excitability level. For example, in up-and-down states membrane potential switches periodically between depolarized and hyperpolarized states inducing simultaneously slow LFP oscillations (<10 Hz) and alternations in firing rates. Here, modulations in unit activity follow the phase of the slow

oscillations, but they are linked only through an external factor – fluctuations in the membrane potential (Fig. 1b; Destexhe et al. 1999). Similarly, slow shifts in excitability may explain relation between phase of low-frequency LFP and firing rate (discussed above), both of which are under control of sensory inputs and fluctuations in ongoing network activity (Mazzoni et al. 2010).

Effects of Neuronal Correlations on LFP-Spike Relation

LFP amplitude is far more sensitive to correlations between neurons than to the number of active units and their firing rate. For example, simulations show that if cell-to-cell correlations increase just by 2% high-gamma LFP power rises by a factor that would normally require ten-fold increase in firing rate of uncorrelated population (Ray et al. 2008). As discussed above, strong synchrony within the population may produce macroscopic “population spikes,” but even a small neuronal assembly can generate a synchronous event (“unitary event”) that is related to a distinct temporal pattern in LFP (Denker et al. 2011).

One particularly useful technique to investigate field-unit relation is to correlate field potential and single-unit spikes by means of spike-triggered averaging (Fig. 1b). Interestingly, the magnitude and waveform of spike-triggered LFP in low and gamma frequency bands (<20 and 25–75 Hz, respectively) correspond more closely to the dynamics of synchrony between the synaptic inputs rather than to network events associated with spikes (Okun et al. 2010).

Temporal correlations between spikes of single units may also produce small but detectable change in LFP signal. For example, a burst of spikes generated by a single neuron can induce a switch of cortical state and corresponding change in the LFP spectrum (Li et al. 2009). Similarly, sensory-evoked spikes in somatosensory cortex are organized in stereotypical spike burst patterns whose incidence covary with the amplitude of high-frequency EEG burst (>400 Hz, Fig. 1a; Telenczuk et al. 2011, 2017b).

Neuronal correlations are under control of brain states, such as different arousal and attention levels. Consequently, the brain states have large impact on the LFP–unit relation. Specifically, spikes elicited in slow-wave sleep are associated with LFP deflections of longer durations and broader spatial coherence compared to waking and REM sleep (Fig. 1b, c; Destexhe et al. 1999).

Other Factors Influencing LFP-Unit Relation

Neural anatomy and micro-architecture determine the physical aspects of LFP generation. The neuronal morphology (Murakami and Okada 2006), geometry of cortical circuits (Buzsáki et al. 2012), and local circuitry may affect LFP in all frequency bands. In addition, the composition of neural tissue such as presence of neurons of different types, glial cells, and vasculature affects the conductive properties of the medium (Nelson et al. 2013). Therefore, the quantitative and qualitative aspects of LFP relationship with unit activity must be always considered in the context of the specific brain area.

Further, the experimental protocol and recording system are the key features determining the LFP and their relationship to unit and synaptic activity. In particular, the type of stimulation is essential in shaping the spatial and temporal properties of spike-triggered LFP (Nauhaus et al. 2009; Reimann et al. 2013). Other factors include: the type of electrodes, analog and digital filters, tissue preparation, position of signal, and reference electrodes.

Implications for Electrophysiology

Unit-related LFP components offer an excellent opportunity for electrophysiologists to study the output of neuronal computation, the spiking, in anesthetized and behaving animals or even noninvasively in humans. Population firing rate and synchrony are two properties that can be currently assessed by means of LFP and

the list may increase as we learn more about the physical and physiological basis of LFP generation.

Synonyms

Coherence of local field potentials; Coupling of local field potentials; Cross-correlation of local field potentials

Definition

The synchrony of local field potentials (LFP) is a neurophysiological property that represents the

correlated activity in simultaneously recorded networks. Its measurement indicates how tightly multiple local networks are coupled. LFP synchrony indicates a potential interaction between the recorded sites and represents a possible mechanism to facilitate synaptic transmission and network-to-network communication.

Detailed Description

The Neural Basis of Local Field Potentials

As elaborated in the companion entry (► [“Local Field Potentials: LFP”](#)), local field potentials (LFPs) represent the summed voltage fluctuations among a population of cells within a given field and are measured with electrodes inserted in the extracellular space of brain tissues. Each neuron’s intracellular membrane potential provides an indication of its excitability and its readiness to fire. Under a barrage of constant inputs, these small intracellular synaptic voltage fluctuations from a population of cells combine together into a spatiotemporally integrated signal which is recorded using low-impedance electrodes. Much like electroencephalography (EEG), the LFP thus represents the compound activity from multiple postsynaptic potentials and provides an integrated electrical signal recorded from the local population of neurons. When recording the LFP activity from multiple regions simultaneously, neurophysiologists can compare the changing patterns of activity in time, studying both the presence and characteristics of oscillations within each area and the changes in synchrony between areas.

Local Field Potential Oscillations

Activity of neurons around an electrode can temporally coordinate into a series of alternating membrane potentials, giving rise to LFP oscillations. These oscillations are often classified into distinctive frequency bands, corresponding to different cycle times. Oscillatory activity is mediated by local circuit properties and by large-scale network inputs. Neuronal firing patterns can become phase-locked to the collective rhythm of the LFP, defining a pattern of population activity (Fig. 1c). LFP oscillations can therefore modulate spiking

Local Field Potential, Synchrony of,
Fig. 1 Theoretical mechanism for network-to-network communication between distant areas. (a) An example of an oscillating network a and a desynchronized network a' where information transfer is prevented between the two. The random variability of a' produces a low-amplitude cross-correlation. (b) Perfect signal synchrony from oscillatory activity between distant networks b and

b' . The phase-locking facilitates information transfer and produces a cross-correlation with a maximal amplitude of 1. (c) The LFP oscillations can modulate intracellular activity with high temporal fidelity, and neural firing can become phase-locked to the collective rhythm of the LFP. In this example, we demonstrate a neuron's burst firing around the peak of the oscillation

activity with high temporal fidelity (organizing spike trains between networks), thus providing a structure for sharing information and favoring network-to-network communication. In the study of LFP and EEG signals, specific patterns of stable oscillations have emerged at different time-scales and for many brain areas. These oscillations have been classified into several frequency ranges: slow ($\sim <1$ Hz), delta (0.1–3 Hz), theta (4–7 Hz), alpha (8–13 Hz), beta (14–30 Hz), and gamma (30–80 Hz) (Traub and Whittington 2010). LFP oscillations can be related to network

interactions that hold information about cognitive and behavioral states of an animal or individual. As mentioned in companion entries, for example, slower beta oscillations occur in the visual cortex in the absence of stimuli, whereas faster gamma oscillations arise in response to stimuli. In addition, beta oscillations in the motor cortex peak in power just prior to movement onset, possibly representing a critical state of the local network required for processing that motor command. As such, oscillations can be initiated or entrained following external stimuli, or they can be

generated internally and modulated in a brain state-dependent manner, such as with attention.

Oscillations Facilitate Synchrony and Connectivity

The presence of oscillations does not necessarily guarantee synchrony but may facilitate it. In the central nervous system, where information is encoded as fast as on a millisecond scale, a mechanism to control inter-network timing is fundamental as a support for the accurate information transfer. Coherent oscillations could provide such a mechanism and appear especially useful in coordinating the timing of activity and strengthening the functional link between distant areas. For example, in spike-timing-dependent plasticity, the strength of connectivity between two neurons depends on the order of firing and the delay between spikes within each pair. An ideal mechanism for coordinating this interaction is if both cells are entrained by oscillating network activity. On a larger scale, we can infer that if those cells participate in oscillatory networks that are coherent, the connection between the two cells would be strengthened or weakened (Cannon et al. 2014).

Parameters for Synchrony of LFPs

LFP oscillations have been associated with various behavioral operations, such as sensory processing, motor planning, attention, expectancy, and cognition. In each of these situations, oscillations serve an underlying mechanistic purpose, serving to bring neural populations together via optimal timing. Indeed, synchrony between LFPs recorded in two different neuronal populations could tighten the coupling and communication between them (see Fig. 1). The theory that synchrony enables communication has been supported both by computational and experimental studies and most effectively described in the neocortex and hippocampus (Fries 2015; Maris et al. 2016). Computational models representing phase-locked oscillating neural systems quantified this facilitation and showed that more information is transferred between neural populations when they are phase-locked and a faster response is generated from one to the next (Buehlmann and

Deco 2010). This information transfer occurs at a cellular level, where the timing and rate of neuronal firing within the two populations are influenced by the population activity, as recorded with LFPs. If the two populations show similar resonant or oscillatory properties, then the likelihood of synchrony and information transfer is greater.

In single-cell patch-clamp recordings, the influence of the LFP on cell activity is made evident in pyramidal neurons by their increased spike probability to input currents when they are oscillating at subthreshold potentials. These oscillations also provide precise temporal windows when spikes are most likely to occur, during the more depolarized membrane state (Traub and Whittington 2010). This phenomenon has been replicated in vivo, where the timing of afferent inputs, with respect to the phase of the oscillation, is an important predictor of the timing of spike output (Cardin et al. 2009). If synaptic input arrives at the peak of a depolarized state, larger responses, with very short time delays, will be produced. On the other hand, if synaptic input occurs at the hyperpolarized phase, spiking output is less likely or is delayed. Following this principle, in a large-scale network of oscillating neurons, propagation of spike output from one local network to the next will occur faster and more robustly (see ► [“Local Field Potential, Relationship to Unit Activity”](#)).

Some neurons also act like important nodes in establishing network synchrony. This is the case in the visual cortex, where coherence in the gamma range modulates sensory processing. Synaptic connections between the excitatory pyramidal cells and the fast-spiking inhibitory interneurons (basket cells) contribute to the development of gamma (>30 Hz) oscillatory activity in the neocortex and the hippocampus (Cardin et al. 2009). These interneurons often fire in a rhythmic pattern, triggering repeated inhibitory postsynaptic potentials (IPSPs) on their efferent pyramidal cells. This pattern can be modulated by feedback from the pyramidal cells within the local network, which send axon collaterals back to the interneurons. The basket cells are also interconnected through gap junctions, and these can determine

network synchrony through rapid spread of current and enhanced neuron coupling. Gap junctions allow a network of interneurons to temporally correlate their firing, causing the spread of synchronous inhibitory currents, compounding their effect on the local projection neurons. The role of gap junctions is also considered important in contributing to LFP oscillations in other areas such as the cerebellum (Robinson et al. 2017).

As LFP synchrony can provide a measure of coupling and a functional link between networks, lack of synchrony can also indicate how networks can remain independent (Fig. 1a). This population selection could be due to circuit properties that determine predominant resonant frequencies, where networks with similar properties would tend to exchange information. Resonance is a property where a group of neurons have a tendency to remain in oscillation for a period of time, in an amplitude- and frequency-dependent manner. This property allows neurons to selectively react to different patterns of inputs, where a greater response will be generated if the input frequency is close to the intrinsic frequency of the local network. Cellular components that enable circuits to function under preferred resonant frequencies are determined by complex interactions between membrane impedance, leak currents, and the different ionic currents produced when the various postsynaptic neurotransmitter receptors are activated (Hutcheon and Yarom 2000; Buehlmann and Deco 2010). These features can also allow more than one predominant resonant frequency within each circuit (Helfrich et al. 2016).

Functionally, LFP oscillations can act as a mechanism to facilitate information processing and communication between distant networks through synchrony. The synchronization of networks is developed through a combination of intrinsic network properties, such as cell-to-cell interactions and resonant properties. This allows for the possibility of altering communication pathways without affecting the anatomical connections. Since neurons have widespread connections, neural populations may alter their phase relation to synchronize with either the output target or input source for optimal communication.

This theory is supported by long-term potentiation (LTP) mechanisms where synchrony in spiking brings an increase in synaptic strength.

Examples When LFPs Synchronize

Synchrony of local circuits plays a role in sensory processing, motor execution, and cognition. To explore this role, electrophysiologists have simultaneously recorded LFPs within multiple cortical and subcortical sites in an attempt to define synchrony patterns across a variety of tasks. Examples of synchrony during sensory binding and sensorimotor coupling, where the synchrony of LFPs seems to improve information processing, are given below. In general, the communication pathways would be enhanced by the synchronization of LFPs between functionally related networks.

Sensory Binding

Synchrony of LFP oscillations may provide the link between single-cell activity and complex computations. In visual perception, recognition of a particular stimulus relies on the coordinated response of multiple cortical areas. Multiple areas in the visual cortex are required to perceive shape, color, position, and direction in order to create a unified percept of the visual scene. The cell assembly responsible for processing a particular object is thus large and distributed over many areas. In order to distinguish distinct visual features, each population of neurons involved in the complete representation of that feature must fire with a coordinated and discrete temporal coding. LFP oscillations and their synchrony could coordinate the neural populations required for this sensory binding. As the visual stimulus is presented, synchronized oscillations in the gamma range serve to coordinate the local activity from each of the subpopulations of neurons involved in processing that stimulus. This synchronized activity then facilitates the transfer of relevant information upstream for further processing (Engel and Singer 2001).

Internally generated brain states can change the dynamic coupling between brain areas, such as during attentional processing and expectation. Intrinsic network operations related to mental

states and sensory input processing can influence synchronization. These interactions give rise to stronger representations and could subserve conscious perception. For example, a sensory experience becomes more salient as the intensity of the stimulus increases. This is reflected in the brain by an increase in gamma oscillations. Similarly, with increased attention allocated to a stimulus, an observer becomes more aware of it, which is also accompanied with an increase in synchronous gamma oscillations (Engel and Singer 2001). An increase in gamma coherence is also experienced when the individual is expecting a precise stimulus and is attentively waiting for its occurrence. This can be recorded prior to stimulus onset and is believed to improve the flow of information through the cortex. In sum, during sensory processing, the level of synchrony is correlated with the perceived strength of the stimuli. Synchrony may also be involved in the selection of relevant information and in preparing the necessary pathways required for producing the most effective responses as efficiently as possible.

Most perceptual experiences involve multiple sensory modalities, and object recognition can require multisensory integration. For example, we may recognize parchment paper not only by its dry, smooth touch but also by the crisp sounds it makes as we feel it. Holding the paper between our fingers, these two sensations are experienced simultaneously, so we link the sound and touch together into one perceptual experience. This link between sensory modalities impacts sensory processing at the network level. For example, somatosensory stimulation received at exactly the same time as an auditory tone has a greater than additive effect on the primary auditory cortex than either stimulus alone, by increasing both oscillations and neuronal spike rate (Schroeder and Lakatos 2009). Delivered at different phases, somatosensory stimulation also has the ability to reset the phase of oscillations in the auditory cortex, after which neuronal firing is enhanced. When trying to understand a person talking in a noisy room, it is easier if we can see their mouth as they speak; this could be because the combination of sensory inputs, along with our increased attention on the subject, may actually change the way our

neuronal populations are synchronizing, facilitating processing of the sounds. This neuronal population synchrony can be witnessed when measuring EEG or LFP signals, with further fine-grained information coming from the rate and phase of neuronal firing.

Sensorimotor Coupling

Performing complex movements, in a coordinated and precisely timed manner, requires organized firing patterns between multiple brain areas. Sensory information must be optimally integrated, or filtered, so that we can navigate within environmental constraints and meet performance demands as successfully as possible. Sensory integration often combines information from vision, proprioception, and touch to guide the limbs and accurately reach targets. To achieve this, the production of movement requires the integration of information from multiple sensory and motor areas, including the cerebral cortex, basal ganglia, and cerebellum. The coordinated interplay between these areas is likely based on synchronized oscillations.

Simultaneously recording LFP oscillations and evaluating the synchrony between sensory and motor areas during sensorimotor tasks may provide information on the coupling dynamics of different neural populations involved in the production of movements best adapted to the sensory input. These wide-ranging networks can change their dynamics on very short (millisecond) time-scale. For example, in a visuomotor integration task in cats, LFP synchrony between the visual, parietal, and motor cortex is modulated on a fine temporal scale as the coupling between these areas shifts throughout the different phases of the sensorimotor task. This modulation follows the information processing demands of the areas involved in the sharing of information; the underlying neuronal activity coordinates so that the greatest synchronization occurs in cell populations more closely related in function than in spatial vicinity (Roelfsema et al. 1997). Thus, the emphasis is on linking neuronal populations that are exchanging information at a given moment. Examining changes in the coupling between LFP signals, and their oscillations, in

more distant areas may tell us how behaviorally relevant sensory information is integrated to produce coordinated motor output.

In LFPs recorded in primates, oscillations between 10 and 25 Hz are present in sensorimotor areas prior to voluntary arm movement. The strength of these oscillations and their coherence are modulated according to the type of task being performed and throughout different phases within each trial. For example, active expectancy and passive expectancy differentially increase the synchrony across the cerebellum between 10 and 25 Hz. In an active expectancy task, the animal has to press a lever to receive a reward, which increases synchrony in the coronal direction more than in the sagittal direction. This increase in synchrony is not present to the same extent during passive expectancy, when the animal did not have to move to get the reward. Similarly, a lever-press sensorimotor task has been shown to increase coherence between the cerebellum, primary somatosensory cortex, and primary motor cortex prior to movement onset (Fig. 2). This synchrony is present in both the active and passive tasks, which may suggest a coordinating role of attention or a gating of behaviorally relevant information (Courtemanche and Lamarre 2005; Courtemanche et al. 2009).

Sensorimotor coupling in humans has been recorded using EEG. This synchrony is modulated in many behavioral conditions, including during learning and memory, and may predict performance. During learning of a bimanual task, such as in a series of finger sequences using both hands, synchrony between the left and right cortices is increased. However, following learning, this synchrony drops to levels similar to tasks requiring only one hand. Similarly, if the cognitive demands of a task are increased, synchrony between sensory and motor areas is enhanced (Hummel and Gerloff 2005). In tasks requiring timed responses, a correlation exists between the speed and accuracy of responses and the level of synchrony between areas involved. This has been demonstrated in both visual- and somatosensory-motor response tasks, where synchrony in beta and gamma range is compared and decreased coupling is associated with slower and less

accurate responses (Womelsdorf et al. 2007). These modulations indicate a specific coordination of task-relevant information requiring multiple brain areas. Synchrony at different frequencies could also determine which operation is taking place, with top-down gathering of information at beta frequencies representing attentional modulation of bottom-up information transfer via synchronous gamma oscillations (Richter et al. 2017).

Measuring Local Field Potentials and Their Synchrony

Local field potentials can be recorded using microelectrode probes of lower impedance (~ 0.3 – 1 M Ω) inserted into the brain tissue and by amplifying the slower frequency bands (e.g., DC–100 Hz). The resulting signal provides a selective window into the slower changes in signal, filtering out the faster changes, such as multiple- or single-unit activity. The sampling frequency should be able to follow millisecond-level changes (1 kHz), especially if fast synchrony changes are to be tracked. With enough bandwidth and sampling frequency, the broadband signal (sub 1 Hz–10 kHz, recorded at 30 kHz) can be initially digitized and stored, permitting off-line extraction of the LFP signal (<100 Hz, decimated) and unit activity (>1 kHz).

LFP signals recorded in close proximity can show a significant amount of similarity across channels throughout various timescales, as can more remote field potentials, though with less probability. This similarity can be noticeable visually but sometimes is difficult to appreciate. Different methods can identify the level of similarity, or level of synchrony of the LFPs, here simplified to the case of two simultaneously recorded LFP signals. One of the first methods, applied in the time domain, is cross-correlation of the two LFP signals. This method identifies the similarity in time between the two signals, with a measure of correlation, at a particular lag time. An example of this is given in Figs. 1 and 2c. Cross-correlation can be normalized to the situation where the two signals are identical, providing a value between -1 and 1 . In this way, the function provides a value of the

Local Field Potential, Synchrony of, Fig. 2 Example modulation and synchronization between the cerebellum and the cortex during a sensorimotor task. (a) LFP traces recorded simultaneously in the cerebellum and primary sensory cortex (S1), with a timeline showing the appearance of the sound stimulus lasting 1.5 s and movement onset – the lever press (arrows indicate onset). (b) FFTs of the corresponding period highlighted in A. The blue line corresponds to the cerebellar trace and the red line

to the cortical trace. These FFTs highlight a common frequency content at 18 Hz at both sites prior to movement onset. (c) Cross-correlation-coefficient functions corresponding to 250 ms windows pre-stimulus and pre-movement. Note the heightened synchronization that accompanies the 18 Hz oscillations during the pre-movement epoch. (Modified from Courtemanche and Lamarre 2005)

coupling strength of the signals and a delay between them. In many situations, the delay or phase will be at zero, where the changes in signals are happening at exactly the same time. Low correlations are often associated with a variable lag. Cases where the lag is of a stable value other than zero can provide insight into the connectivity between the two sites.

A second method, called coherence, is applied in the frequency domain. This method identifies the commonality between signals across their frequency bands, highlighting the common frequency components in both signals. Coherence is expressed from 0 to 1.0, with higher values for more coherent signals. An example is given in Fig. 3a, which represents the coherence between

Local Field Potential, Synchrony of,
Fig. 3 Example of coherence compared across sites and conditions in the cerebellum and prefrontal cortex in the rat. (a) Coherence between the left and right hemispheres of the prefrontal cortex (blue lines) and between the right cerebellum and left prefrontal cortex (orange lines). Also shown here is the coherence preceding (solid line) and following (dashed line) electrical stimulation of the medial cerebellum. Shaded areas represent pertinent frequency bands. (b) The integrated coherence represents the area under the coherence curves in each frequency band (shaded areas in a). The average of pre- and poststimulation values of integrated coherence is shown in this bar graph. (c) The relative changes (in %) in coherence between pre-stimulation and poststimulation integrated coherence. Comparison sites are illustrated below

left and right prefrontal cortex LFPs, as well as coherence between the cerebellum and the contralateral prefrontal cortex, as a function of frequency, in an anesthetized rat. Coherence is greater intracortically than between the cerebellum and prefrontal cortex LFPs. Coherence can also be compared across different conditions or following experimental manipulations, such as when delivering electrical stimulatory pulses. Integrating the coherence curve between two frequencies provides a way to quantify coherence bands between two LFPs, as shown in Fig. 3b. Coherence decreased slightly in all frequency bands following stimulation but more significantly in the alpha band (nearly 15%) (Fig. 3c).

Finally, a third method that can identify synchrony is directed coherence. An elaborate description of Granger causality methods is given in another entry (► [“Spectral Interdependency Methods”](#)). Briefly, this method has similarities with the basic coherence analysis but also exposes the direction of information flow. This is done by comparing the estimated fraction of the signal around a particular frequency across LFPs but makes different comparisons in time. One LFP is separately compared to the current and previous values of the other LFPs and vice versa, in order to determine if the timing of one precedes the other. This last method allows one to determine which signal potentially drives the other one (Baccala and Sameshima 1999).

Overall, the synchrony of local field potentials is a phenomenon that can provide valuable information about network organization and communication during behavior. The technique has been around for a while, akin to some of the first recordings done in the nervous system. The new electrophysiological techniques that are now available have identified more precisely the microscale network components, from cells to some of their constituent parts. Coupled with those microscale techniques, local field potential synchrony can provide a more complete understanding of network-level organization. Combining those techniques will hopefully lead to a new understanding of brain functions with functional applications in brain-machine interfaces and neuroprosthetics.

Local Field Potential: Relationship to Membrane Synaptic Potentials

Aryeh H. Taub¹, Ilan Lampl¹ and Michael Okun²

²Centre for Systems Neuroscience and Department of Neuroscience, Psychology and Behaviour, University of Leicester, Leicester, UK

Definition

The relationship between the somatic membrane potential of an individual neuron and the local field potential signals, assessed by cross-correlation, coherence, or related statistical analysis methods. Typically, correlation between these two signals exists due to synaptic inputs shared by the individual neuron and the entire neuronal population.

Detailed Description

The membrane potential (Vm) of neurons is shaped by transmembrane flow of ions, which

can have both synaptic and intrinsic origins. A net flow of current across the membrane produces, in addition to the change in Vm, a small change in the potential of the extracellular medium outside the cell, which can be picked up by an extracellular microelectrode. The low-frequency (<300 Hz) component of this signal, known as the extracellular local field potential (LFP), is produced by transmembrane currents flowing simultaneously in thousands of neuron and glial cells, superimposed according to the complex spatiotemporal profile of neuronal activity. Thus, unlike Vm, which is determined by processes pertaining to that particular cell, the LFP depends on the morphology of the cells, the spatial distribution of the contributing ion channels, and the temporal coordination of the currents as well as on the spatial organization of the cells.

As both Vm and LFP fluctuations originate in transmembrane electric currents, it is reasonable to find at least some correlation between the sub-threshold (Vm) or the suprathreshold (spiking) activity of individual neurons and the nearby LFP. In cortex, Vm-LFP correlations were indeed observed in pioneering experiments in the 1960s, in which intracellular potential of individual neurons (observed using sharp recording pipettes) and nearby surface LFP (see entry ► [“Electrocorticogram \(ECoG\)”](#)) were simultaneously recorded in the visual and sensorimotor cortices of cats and rabbits (Creutzfeldt et al. 1964, 1966; Klee et al. 1965). These early experiments were performed under deep anesthesia, which strengthens the synchrony in cortical networks and thus in particular increases the correlation between Vm and LFP signals, making Vm-LFP correlation easier to detect.

Since the days of these early experiments, new technologies were developed to monitor the membrane potential of individual neurons and of neuronal populations. These include the whole-cell patch recording and approaches such as voltage-sensitive dye (VSD) or voltage-sensitive fluorescent protein (VSFP) imaging. Whereas a considerable amount of experimental in vivo data was acquired over the years through combined intracellular (sharp or whole-cell) and LFP recordings, in both anesthetized and awake

animals, so far only a few studies combined imaging and LFP recording (e.g., Ferezou et al. 2007; Ayzenshtat et al. 2010). Consequently, here we focus exclusively on electrophysiological intracellular and LFP data. We follow the convention according to which LFP refers to the low-frequency ($<100\text{--}300\text{ Hz}$) portion of the extracellular signal, leaving works studying the Vm origins of the extracellular spike signals (Wehr et al. 1999; Henze et al. 2000; Gold et al. 2006; Chorev and Brecht 2012) outside the scope of this entry.

In brain areas such as the cortex, the volume of tissue in the immediate vicinity of an LFP recording site contains many hundreds of neurons. Therefore, experimentally observed significant correlation between the LFP and the Vm of individual nearby neurons indicates that the Vm of most or possibly even all nearby neurons is correlated with the LFP (suggesting in particular that the Vm of nearby neurons is correlated as well (Lampl et al. 1999)). The LFPs commonly observed in the cortex and hippocampus are on the order of $0.1\text{--}1\text{ mV}$ in amplitude and 3–4 orders of magnitude higher than those produced and observed extracellularly by single synapses (Glickfeld et al. 2009; Lindén et al. 2010), which is consistent with the LFP being a product of synchronized activity of thousands of synapses belonging to a large group of neurons.

In the simplest scenario, when the paired Vm and LFP recordings are made in the same cortical column and layer, the recorded cell is part of a local ensemble of neurons, all of which simultaneously receive synaptic input barrages. These barrages are seen both as postsynaptic potentials (PSPs) in the Vm and as LFP events reflecting the intracellular PSPs simultaneously happening in the entire ensemble. However, Vm-LFP correlations that are a pure result of such local activity, independent of nearby columns, layers, or areas, are unlikely to exist due to a number of reasons. To begin with, the LFP signal is “contaminated” by volume-conducted events remote from the LFP recording site, e.g., (Kajikawa and Schroeder 2011; Carmichael et al. 2017; Kajikawa et al. 2017; Parabucki and Lampl 2017). Furthermore, the neuronal activity consists not only of localized

barrages received by specific ensembles but also of large waves of synaptic activity that reach the LFP site either simultaneously with reaching the intracellularly recorded neuron (for a standing wave) or with some positive or negative delay (for a propagating wave). In this case, the extracellular LFP fingerprint of the event is a complex combination of the synaptic activity at the LFP recording site with the conducted activity from the surrounding volume. The interpretation of Vm-LFP coupling can be further complicated by the non-synaptic component of both Vm and LFP. One possible way to disentangle some of the different sources contributing to the LFP and thus to Vm-LFP coupling is current source density (CSD) analysis (see entry ► [“Current Source Density \(CSD\) Analysis”](#)), e.g., through recording the LFP at multiple nearby sites with a multi-channel silicon probe. Unfortunately, so far very few studies combined recordings amenable to CSD analysis with simultaneous Vm recordings (one such example is the study of Quilichini et al. (2010) in the entorhinal cortex).

In an entirely different scenario, the Vm and LFP recording sites are far apart, e.g., in different brain structures (specific examples will be mentioned below). In this case, the synapses driving the Vm fluctuations cannot be “felt” by the LFP recording electrode, and vice versa, any synaptic activity driving the LFP is unrelated to the synaptic inputs of the intracellularly recorded neuron. In this case, therefore, any correlation between Vm and LFP is due to temporally synchronized but anatomically distinct synaptic inputs, or alternatively they may be correlated due to volume conductance.

Quantitative Description of Vm-LFP Correlation

Both Vm and LFP are univariate analog signals, so that the most straightforward way to measure the relationship between the two is to compute their cross-correlogram (Fig. 1e). In the cortex, where LFP events are seen as depth-negative bumps, the cross-correlation of nearby Vm and LFP signals (with Vm taken as the reference signal) typically has a unimodal peak pointing downward. The exact shape of the cross-correlogram

Local Field Potential: Relationship to Membrane Synaptic Potentials, Fig. 1 Vm and LFP during synchronized Up-Down activity. (a) 20 s trace of Vm and LFP recorded ~0.3 mm apart in the barrel cortex of

anesthetized rat. (b, c) Power spectrum density and autocorrelation of the Vm and LFP signals. (d, e) Vm-LFP coherence and cross-correlation (Vm was preprocessed by clipping the spikes and high-pass filtering above 5 Hz)

depends on other factors such as the location of the two recording electrodes and the type of activity (see below).

Both the Vm and the LFP have a $1/f$ power spectrum (more precisely $const/f^\alpha$ where the α coefficient need not be the same for the two signals), and most of the power of the signals is in low frequencies, which in particular implies that the Vm-LFP cross-correlation primarily reflects the low-frequency components of the two signals. Coherence analysis (Fig. 1d) is typically used to detect correlation in frequencies higher than 10–20 Hz. More advanced methods (e.g., ►“Spectral Methods in Neural Data Analysis:

Overview” (Haider et al. 2016)) can be applied as well, however will not be reviewed here.

There are several technical caveats one needs to keep in mind when estimating the Vm-LFP relationship in experimental data. First, the LFP signal can often be contaminated by volume conduction, as mentioned above. Second, whereas intracellular amplifiers typically measure the Vm in DC mode, or have a high-pass filter with a rather low cutoff frequency (e.g., 0.01 Hz), extracellular amplifiers used for measuring LFPs typically have high-pass filter with a much higher cutoff frequency, often distorting measurements at frequencies as high as 1–3 Hz (Nelson et al.

2008). If this is not corrected, Vm-LFP and spike-LFP cross-correlation will have a bimodal waveform, with negative value around 0 time lag and positive correlation ensuing 50–500 ms later (Okun 2017).

Vm-LFP Correlation during Synchronized Cortical Activity

Vm and LFP correlation was primarily investigated in the cortex. Here, synchronized Up-Down activity (see entry ► “[Low Frequency Oscillations \(Anesthesia and Sleep\): Overview](#)”) during certain anesthesia regimes, during slow-wave sleep, and during quiet wakefulness (at least in rodents) is the most prominent intracellular activity pattern. Slow oscillations were extensively studied using intracellular, extracellular, and combined recordings. It was established that the cycles are typically 100–1000 ms in duration, with Up states characterized by spiking activity induced by barrages of synaptic inputs causing the Vm of individual neurons to depolarize by 10–20 mV relative to the silent Down baseline. When Up states last for ~300–500 ms and above, the Vm distribution is typically bimodal. In the Up-Down activity mode, large areas of the cortex get activated and deactivated almost simultaneously, so that pairs of intracellularly recorded neurons up to ~1 cm apart exhibit delays of just a few ms (Volgushev et al. 2011), while LFPs separated by 0.5–1 cm are remarkably similar to each other (Destexhe et al. 1999).

The synchronous activity across large areas of the cortex produces very large LFP waves (1–2 mV in the subgranular layers), which at the Up-state onset are positive at the surface and the superficial cortical layer and negative in the deep layers (i.e., a current sink in deep layers and a current source near the cortical surface). Up onsets and offsets are readily seen in both Vm and LFP (Fig. 1a). Due to the synchronization of the Up-Down fluctuations across relatively large distances, the Vm-LFP correlation is dominated by Up and Down transitions. Typically, the Vm-LFP cross-correlation relaxes to its nonsignificant baseline level within several hundreds of milliseconds, reflecting the long time constant of Up-Down activity. Furthermore, it is possible to

predict the onset and offset of the intracellular Up states from the LFP signal (Mukovski et al. 2007; Saleem et al. 2010).

Cortical slow oscillation is correlated across the two hemispheres and with dynamics in other brain structures such as the thalamus (Contreras and Steriade 1995; Rigas and Castro-Alamancos 2007; Hirata and Castro-Alamancos 2010) and the entorhinal-hippocampal circuits. In the hippocampus, there is an interesting difference between the behavior of pyramidal cells and interneurons: whereas pyramidal cells do not exhibit bimodal fluctuations in their Vm, some populations of hippocampal interneurons do participate in the slow oscillation, which was established through experiments that employed simultaneous recordings of cortical LFP and Vm of neurons in hippocampus or entorhinal cortex (Hahn et al. 2006, 2012; Isomura et al. 2006).

Cortical Vm-LFP Correlation During Active Wakefulness and Sensation

Intracellular recordings in the cortex of awake mammals performed together with nearby LFP recording indicate that during active waking, and in particular active sensation, the slow oscillations are replaced by a desynchronized state which to a first approximation resembles a continuous Up state (Destexhe et al. 2007; Poulet and Petersen 2008; Tan et al. 2014). A similar shift is also observed in relatively light anesthesia states. In this “activated” condition, Vm and LFP retain some degree of synchronization, which is lower than for the synchronized state of slow oscillations. This lower correlation reflects the absence of the Up and Down transitions. Interpretation of Vm-LFP correlation in the desynchronized cortex is less straightforward than for Up-Down activity. The Vm of nearby neurons is correlated to some degree even in the active condition (Poulet and Petersen 2008; Volgushev et al. 2011), indicating that some degree of synchrony exists in the activity of synapses in small cortical volumes, which is the most likely cause of the statistically significant Vm-LFP cross-correlation. However, unlike Up-Down activity, where the entire population is entrained, here we do not know which neurons are synchronized, and in fact it is plausible that the

populations (ensembles) of neurons that do synchronize change, possibly many times each second. The nonlocalized spatial origins of single-electrode LFP measurements do not allow answering this question.

Correlation between Vm and LFP activity evoked by discrete sensory inputs was examined in additional studies, carried out in the primary sensory cortical areas of anesthetized and awake rodents (Deweese and Zador 2004; Haider et al. 2016). These studies showed that a large portion of the trial-to-trial variability of the subthreshold sensory response observed in whole-cell recordings is accounted for by variability in the evoked LFP response, consistent with the idea that the sensory evoked PSP in single neurons arises from a network-level response event.

LFP, Spikes, and Excitatory and Inhibitory Synaptic Inputs

Because pyramidal cells are extended in space, whereas interneurons have a compact morphology, LFP is primarily generated by currents in pyramidal cells. Furthermore, under normal physiological conditions, these currents are first and foremost a result of synaptic activity (Buzsáki et al. 2012). The synaptic currents can be either excitatory or inhibitory. In the cortex, the excitatory and inhibitory inputs to individual neurons are to a first approximation balanced in time and strength; therefore, both excitatory and inhibitory currents contribute to the LFP. However, due to a range of factors, the LFP mainly reflects excitatory synaptic currents (in excitatory neurons). To begin with, the resting potential of cortical neurons is much closer to the reversal potential of inhibition; thus, the very same excitatory or inhibitory synaptic conductance produces synaptic currents that are several times bigger for excitation. Moreover, a large proportion of inhibitory inputs (presumably those that originate from fast-spiking neurons) are more proximal to the soma (Kawaguchi and Kondo 2002; Yoshimura and Callaway 2005; Sun et al. 2006), creating only a small dipole. Finally, inhibitory synapses depress significantly more than excitatory synapses (Heiss et al. 2008; Cohen-Kashi Malina et al. 2013) and

thus may contribute significantly less to the LFP signal. A recent study of the correlation of LFP with excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) found that it is of approximately equal magnitude to LFP correlation with Vm (Haider et al. 2016).

In several studies of correlation between excitation and inhibition in the gamma frequency range, LFP was used as a reference signal. The goal of these studies was to understand the temporal relationship between the excitatory and inhibitory inputs, the problem being that an intracellular recording allows to measure either the EPSCs (when the cell is hyperpolarized) or IPSCs (when the cell is depolarized), but not both of them simultaneously. One approach to tackle this difficulty is to record from pairs of nearby neurons (Okun and Lampl 2008). However, for the purpose of establishing the average relationship between the EPSCs and IPSCs, it is sufficient to correlate each of them separately with a nearby LFP (Fig. 2).

Finally, let us move from the correlation between synaptic inputs to individual neurons and the LFP to briefly describe the relationship between the LFP and neurons' output, i.e., spikes. The correlation between LFP and spikes, typically quantified by the spike-triggered LFP average (stLFP, see entries ► [“Phase-Locking Methods”](#) and ► [“Local Field Potential, Relationship to Unit Activity”](#)), is determined by the Vm dynamics of the neuron. If spiking is considered to be simple threshold crossing detection, then stLFP would be expected to be proportional to Vm-LFP correlation (Boer and Kuyper 1968). Our study comparing stLFP with Vm-LFP correlation in awake rat cortex showed that indeed the stLFP does reflect the underlying Vm-LFP cross-correlation in terms of both its temporal waveform and its magnitude (Okun et al. 2010). These findings provide direct evidence for the commonly held view that the correlation between spikes and LFP reflects synchrony between the synaptic inputs that drive the membrane potential fluctuations of the neuron and the synaptic activity in the local network. Furthermore, the similarity between Vm-LFP cross-correlation and stLFP suggests that the Vm to spike transformation does not alter the

Local Field Potential: Relationship to Membrane Synaptic Potentials, Fig. 2 LFP as a reference signal allowing to resolve the excitatory-inhibitory dynamics. (a, b) Simultaneous LFP (broadband and 30–80 Hz band-pass filter) and Vm recording in prefrontal cortex of an anesthetized ferret. The Vm was recorded in two conditions: a hyperpolarized condition revealing excitatory inputs (a) and a depolarized condition revealing inhibitory inputs (b). (c, d) Part of the traces in (a, b) on an expanded timescale. (e) Average of Vm in hyperpolarized and depolarized conditions, triggered by the trough of the LFP gamma oscillation. This analysis reveals that both excitatory and inhibitory inputs are modulated by gamma

oscillations but have opposing phases. (f) Simultaneous LFP and Vm recording in hippocampal CA3 region of an anesthetized rat. As in (a, b), the Vm was recorded in hyperpolarized and depolarized conditions. (g) Average of Vm in hyperpolarized and depolarized condition, triggered by LFP gamma oscillation, as in (e). The two averages show that excitatory inputs precede the inhibitory inputs by 1–2 ms. (h) EPSC and IPSC averages triggered by LFP events of different magnitudes, showing that bigger events generate stronger excitatory and inhibitory synaptic inputs (Panels a–e reproduced, with permission, from Hasenstaub et al. (2005). Panels f–h adapted, with permission, from Atallah and Scanziani (2009))

underlying subthreshold correlation between single neurons and the LFP.

Definition

Local field potentials (LFPs) and electroencephalogram (EEG) recordings from many vertebrate and invertebrate olfactory systems show several types of prominent oscillatory features that depend on class, species, learning, and behavioral state. In mammals these oscillations are in three major bands: gamma (30–100 Hz), beta (15–30 Hz), and theta/respiratory (0.5–12 Hz). Modeling efforts are directed at gamma and beta oscillations in the olfactory bulb (OB) and gamma-like oscillations in the insect antennal lobe (AL). In invertebrates and fish, only gamma-like oscillations have been described (20–30 Hz).

Detailed Description

Local field potentials are the summed extracellular voltage fluctuations measured from electrodes placed within an area of the cortex or other brain regions (see entry ► [“Local Field Potentials: LFP”](#)). In cortical systems, with neurons aligned

in parallel, the field is represented by a dipole which reverses at one of the cortical layers. This voltage is often mirrored intracellularly. In non-cortical systems, such as the insect olfactory system, the coherence of the LFP signal across neurons may be poor due to the non-laminar geometry, and the intracellular and extracellular fields may be quite different.

Types of Olfactory LFP Oscillations

When local field potentials are measured in the olfactory system (usually OB and piriform or pyriform cortex (PC) but also including the anterior olfactory nucleus, olfactory tubercle, entorhinal cortex, hippocampus, amygdala, and orbitofrontal cortex), they show robust oscillatory components in several frequency bands. The frequency ranges are variable and depend on the species and behavioral state. The ranges for mammals are listed below, and variances in nonmammalian species are noted where appropriate.

Gamma oscillations (30–100 Hz, depending on the species and behavioral state) were first described in the OB and PC. Two types of olfactory gamma oscillations have been identified. The first, dubbed *gamma1* and also referred to as just “gamma,” is the classic odor-evoked fast oscillation that arises at the transition from inhalation to exhalation (Fig. 1). In the OB, *gamma1* oscillations are generated by the reciprocal dendrodendritic synapse between mitral and granule cells, and mitral/tufted cells’ firing probability over time represents the gamma oscillation (Rojas-Líbano and Kay 2008; Kay et al. 2009). The OB *gamma1* oscillation is one of the most studied brain oscillations, and it is the subject of numerous modeling efforts. Similar oscillations are present in the PC, but less is known about the mechanism. Modeling studies suggest the negative feedback interaction between pyramidal cells and inhibitory interneurons can drive gamma in the PC (Freeman 1975). More recently, the *gamma1* band has been subdivided into high- and low-frequency bands. In rats and mice, these sort out into a higher band centered at about 90 Hz that occurs at the transition from inhalation to exhalation and a lower band centered at about

70 Hz that occurs during early exhalation (Manabe and Mori 2013; Frederick et al. 2016).

Many insects (e.g., locusts, honey bees, *Drosophila*) and nonmammalian vertebrates (e.g., zebra fish and frogs) produce an odor-evoked gamma-like oscillation in the antennal lobe (AL) and OB, respectively, also supported by the reciprocal synapse between principal excitatory neurons and GABAergic inhibitory neurons, but the frequency is 10–30 Hz (Kay and Stopfer 2006; Kay 2015). The oscillation in insects is present intracellularly in projection neurons (PNs). Because the AL is non-laminar, the extracellular LFP recorded from this structure does not show prominent oscillations; LFP recorded from the PN axon terminals in the mushroom body shows robust odor-evoked oscillations.

Lower-frequency gamma oscillations (narrow band ~55 Hz), dubbed *gamma2*, have also been described in rats and mice. These oscillations occur only during periods of low respiratory rates in between breaths and show high coherence with similar oscillations in the PC. There is nothing known about the mechanism or functional relevance of these oscillations, although their absence in mice that lack functional GABA_A receptors on OB granule cells suggests that they may require inhibition of the inhibitory interneurons (Kay 2003).

Theta or respiratory oscillations (0.5–12 Hz, depending on behavioral state and species) match the respiratory rhythm in mammals and produce a slower modulation of the field on which gamma oscillations are superimposed. Small rodents (rats and mice) breathe at several frequencies that depend on behavioral state. Under anesthesia the respiratory rhythm is 0.5–1.5 Hz; at rest the frequency is 2–4 Hz; during exploratory behavior, rats sniff at 5–6 Hz; during stationary active sniffing, the frequency is the highest, 7–12 Hz (Welker 1964; Youngentob et al. 1987; Mainland and Sobel 2006; Rojas-Líbano and Kay 2012; Rojas-Líbano et al. 2014). The mammalian gamma oscillation is initiated at the peak of the inhalation cycle and often lasts through most of the exhalation phase. Glomerular circuitry in the OB is believed to support

Local Field Potentials in Olfaction, Fig. 1 Gamma oscillations in the olfactory bulb. (a) Example of gamma oscillations from LFP recording. Respiratory frequency was ~ 4 Hz, rat awake but resting. Gamma oscillations arise at the end of inhalation. (b) Basic OB circuit showing a mitral and tufted cell at the dendrodendritic synapse. It is

this synapse that is responsible for gamma oscillations. (c) Pulse probability represents the probability of a mitral cell spiking given that the LFP is recorded locally. the respiratory oscillation, and there are neurons in the glomerular layer that burst intrinsically at ~ 2 Hz in OB slices (Hayar et al. 2004). Recent studies have shown theta oscillations coherent with hippocampal theta (see entry ► “[Hippocampal Theta, Gamma, and Theta/Gamma Network Models](#)”) within the olfactory bulb in some circumstances and respiratory oscillations driven by the olfactory bulb in the hippocampus in some circumstances (Tort et al. 2018). These oscillations also organize cortical activity in many regions of the cerebrum in humans and rodents (Zelano et al. 2016; Heck et al. 2017).

Beta oscillations (~ 20 Hz; Fig. 2) described in the olfactory system of rats are primarily

associated with specific waking behavioral states. They arise with learning of operant odor associations and are coupled to odor sampling (Martin et al. 2004). Beta oscillations also increase in waking rats upon repeated exposure to highly volatile odors (Lowry and Kay 2007). Gamma oscillations rely on local circuits and increase in amplitude if the OB is isolated from centrifugal input (Gray and Skinner 1988). Beta oscillations depend on the centrifugal input and disappear when this input is temporarily or permanently ablated (Neville and Haberly 2003; Martin et al. 2006). They are highly coherent with simultaneously recorded activity in many parts of the olfactory system, while gamma oscillations are

Local Field Potentials in Olfaction, Fig. 2 Gamma and beta oscillations of the LFP in the OB and PC. Color plots are spectrograms of the OB signal over the 1 s period of the signal displayed below. Gray spots to the right of each plot represent significant coherence between the OB and PC signals at the given frequency, with the size of the spot

representing the magnitude of the coherence. (a) Gamma oscillations elicited during odor sampling show that this oscillatory even is local to the OB, showing very little coherence with the PC. (b) Beta oscillation elicited by an odor shows high coherence between OB and PC. (Figure from Kay et al. 2009, with permission)

not strongly coherent across areas. Three recent modeling studies have addressed possible mechanisms for beta oscillations, and they all focus on conversion of the gamma circuit supported by the reciprocal dendrodendritic synapse (Fourcaud-Trocmé et al. 2011; David et al. 2015; Osinski and Kay 2016). All of these models rely on the ionic currents at the dendrodendritic synapse that change character depending on excitation of granule cells, but they differ in how the transition to and maintenance of beta is supported.

Recording Mammalian Olfactory LFPs

The LFP is the summed local field produced by neurons in the neighborhood of an electrode. Many factors can affect the LFP, from the electrode size and impedance to the areas in the neighborhood of the recording site. Electrode size can influence the area of the tissue over which the signal is collected; different sized electrodes can lead to different results regarding the coherence of the signal across a cortical area. In the OB larger electrodes produce a more coherent signal, but the coherence also changes with cortical depth (Kay and Lazzara 2010). The curvature of cortical areas can also influence the signal recorded with a

standard LFP electrode (50–100- μ m-diameter stainless steel, tungsten, or other metals). If a cortical sheet curves such that the electrode picks up signals from multiple parts of cortex, then the signal may not be representative of a single group of local neurons. Furthermore, if cortical areas or subcortical and cortical areas are close to each other, then the LFP produced in one area can affect that recorded in the other, for which there are several notable examples (Carmichael et al. 2017; Parabucki and Lampl 2017). It is important to note that much of the OB LFP comes from the granule cells, which are arrayed as a sheet of parallel dipoles. Mitral and other cells in the OB have more radial geometry, which makes for a very poor LFP. While all the cells are participating in the population activity that produces oscillations, the signal received by electrodes represents primarily the granule cells' picture of that population event.

There are techniques that can reduce contamination by nearby areas. First, using bipolar electrodes with a tip separation appropriate to straddle the cortical layer of interest allows placement of the two leads perpendicular to the cortical sheet on opposite sides. (See Freeman (1959) for the first

Local Field Potentials in Olfaction, Fig. 3 Simultaneous recordings of OB LFP using 100- μ m-diameter stainless steel wire. Leads were approximately 1 mm apart in cortical depth. The superficial lead was in the glomerular layer, and the deep lead was in the

granule cell layer. The bipolar trace is the result of subtracting the deep from the superficial wave form. Note the artifact at ~ 0.58 s (arrow) that is nearly eliminated in the bipolar trace. Data were sampled at 2020.2 Hz

description of this technique in the PC.) This is especially easy in mammalian olfactory system recordings. In the OB and PC, the respiratory rhythm reverses across the principal cell layer in the three-layered cortex, so placing the one lead in the superficial layer and the other in the deep layer allows visualization of the mirror-image respiratory wave across the two leads (Fig. 3). If the phase difference is close to 180 degrees, then the leads are perpendicular to the cell layer. Alternatively, antidromic stimulation of OB mitral/tufted cells and orthodromic stimulation of PC pyramidal cells by electrical stimulation of the lateral olfactory tract produces a stereotyped oscillatory evoked potential that can be used to position the bipolar recording electrodes in the OB and PC.

Bipolar recordings can be used in two different ways. First, differential recording across the two leads amplifies the part of the signal that is reversed across them and attenuates any part of the signal that is not reversed, so that signals that come from nearby areas will be removed or

attenuated. Second, specific leads can be selected for analysis to normalize positioning of electrodes across subjects. If monopolar recordings are used, the bipolar traces can be examined to determine whether oscillatory events of interest are reversed across the two leads. This can help resolve questions regarding whether a particular event is generated locally or in a nearby area. Differential recording will not change the frequency of the signals but may shift the phase if the reversal across the two leads is not perfect. This will only be a problem if one is studying phase delays between areas.

Determining the Source of an Oscillation

Many different types of experiments converge to explain the sources of olfactory LFP oscillations. These types of studies involve intracellular recordings in brain slices, pharmacological manipulations, computational modeling, extracellular LFP recordings in many behavioral states, and an extension of LFP recordings known as

current source density (CSD) analysis among many others. CSD analysis takes advantage of cortical geometry. In a laminar cortical system, the spatial derivative along the depth axis perpendicular to the pial surface allows one to estimate the sources and sinks of currents supporting a given LFP event (Mitzdorf 1985). By measuring a given type of event simultaneously at many evenly spaced cortical depths, it is possible to estimate the theoretical current flow between cortical layers. There are many assumptions from the ideal case that are violated in real cortical systems, but current source density remains a powerful tool for examining stereotyped LFP events. CSD has been applied to the olfactory system in a handful of publications. Before the easy availability of multichannel recording, easy and cheap data storage, and fast computers for estimating the current flow across many channels, CSD was done using electrical stimulation of the lateral olfactory tract and analysis of the stereotyped electrically evoked potential in the OB at successive depths recorded one at a time ((Martinez and Freeman 1984); Fig. 4a). Because the evoked potential is very stable, given the correct stimulation parameters, this could be done with good confidence. CSD from simultaneous laminar recordings of spontaneous activity in the OB was done in anesthetized rats and confirms the source of gamma oscillations as an alternating source-sink pair in the external plexiform and internal plexiform layers and beta oscillations generated from slightly deeper sublaminae (Neville and Haberly 2003; Fourcaud-Trocmé et al. 2014; Fig. 4b). There are several different methods to compute the CSD, and these are reviewed along with formulation of a new method (inverse CSD/iCSD) in Pettersen et al. (2006).

Evidence for Functional Relevance of Olfactory Oscillations

Several studies give converging support for the functional importance of gamma band oscillations in the olfactory bulb. In the honeybee AL, odor-evoked oscillations can be eliminated by application of picrotoxin, which blocks GABA_A

receptors. This takes the inhibitory drive out of the reciprocal synapse between projection neurons and local neurons. Projection neurons still fire in response to odors, but they are not coordinated in a normal oscillation. This does not make the bees anosmic, but it does make it more difficult for them to discriminate chemically similar odors (Stopfer et al. 1997). In beta3 knockout mice, gamma oscillations are artificially enhanced by knocking out inhibition of granule cells (inhibition onto the main inhibitory local neurons). These mice are better than heterozygous controls at discriminating similar odors (Nusser et al. 2001). Rats that are trained to discriminate odors in an operant discrimination task increase gamma oscillations when they have learned to discriminate very similar odors but not when they discriminate more different odors (Beshel et al. 2007). No other olfactory oscillations have been tested in this way, so functional relevance is unknown for olfactory beta, gamma2, and theta or respiratory oscillations. However, there is converging evidence regarding beta oscillations that begin to point at functional roles. Beta oscillations follow a few sniffs associated with gamma oscillations during odor sampling in an operant task, which suggests that they are better related to system-wide interactions associated with decisions or action than with early sensory processing (Frederick et al. 2016) (Fig. 5).

Note that functional relevance does not mean that the LFP is the mechanism of functionality, only that what the LFP represents is associated with the ability to detect fine differences between odors. The LFP gamma (or gamma-like) oscillation represents the coordinated firing of the principal neurons (mitral/tufted cells or projection neurons). This firing is oscillatory at the level of the group average and is represented by intracellular membrane potential oscillations within mitral cells and projection neurons.

Using the LFP to Infer Neuronal or System Properties

The LFP itself has not been shown to have any causal properties. However, the underlying sets of

Local Field Potentials in Olfaction, Fig. 4 Current source density estimate in the OB. Left: (a) 16 averaged evoked potentials (n=200) recorded from the rabbit olfactory bulb in response to stimulation of the primary olfactory nerve, using a 1×16 electrode array. The recording site for each electrode within the bulbar laminae is indicated by lines drawn to the diagram at left, illustrating the bulbar lamina including the primary olfactory nerve (PON) at the surface, the olfactory glomerulus (dashed circle) with a nearby periglomerular cell (PG), the mitral cell (M), apical dendrite, cell body basal dendrites and axon, and a granule cell (G) interneuron. Abbreviations: GL, glomerular layer; EPL, external plexiform layer; MCL, mitral cell layer; IPL, internal plexiform layer; GRL, granule cell layer. (b) Current source density (CSD) values versus time calculated for nearest neighbor electrodes using the averaged evoked potentials from (a). (c) CSD calculations using the second nearest neighbor electrodes. (Left figure and

excerpted caption from Martinez and Freeman (1984), with permission; figure edited to darken evoked potential curves in (a-c)). Right: CSD analysis in the OB of an anesthetized rat. (A) CSD over time (400 ms) showing a gamma oscillation early and a beta oscillation later; gamma on the peak of a slow inhalation and beta in the trough of exhalation. Full-frequency band on the top, with filtered gamma and beta band CSDs below. Gamma and beta oscillatory signals in red and respiratory wave in black at bottom. GL, glomerular layer; EPL, external plexiform layer; MCL, mitral cell layer; GRL, granule cell layer. (B) Average CSD map of gamma and beta events. Note that gamma appears to be supported by sink/sources in the superficial EPL and the MCL and superficial GRL, while beta shows a sink in the deeper EPL with source in the GRL. Local Field Potentials in Olfaction, Fig. 5 Gamma and beta oscillations in behaving rats. (a) Sample voltage traces showing gamma (red horizontal bars) and beta (blue horizontal bar) oscillations during a single trial. The vertical line at 0 indicates nosepoke-on, with the estimated arrival of the odor stimulus at approximately 60 ms. OB is the top trace and aPC the bottom trace for the raw data. (b) Gamma (top) and beta (bottom) band wavelet plots showing frequency over time from the data in a. Color represents power with red high. Note the sweep in frequency from higher to lower for the first two gamma bursts and the abrupt transition from gamma to beta just after 250 ms. (c) Sample wavelet time-frequency plots showing three session averages (columns represent three different odor sets). (i) OB power: note strong gamma during early odor sampling for the extreme odor set (two different vials containing the same odor with different trace contaminants), lower power gamma and

strong beta for odor set 2 (easily discriminated high volatility odors), and both gamma and beta power for odor set 3 (easily discriminated odors). (ii) aPC power: note the similarity in beta power between OB and aPC. Gamma power in the aPC is much smaller than in the OB. (c.i and c.ii use the same color scale, which is in dimensionless units after normalization and log transform.). (iii) Coherence between OB and aPC shows a decrease in strength during odor sampling in the lower-frequency bands for the extreme odor set, and coherence overall is primarily limited to the beta band. Coherence is represented as Z-coherence (arctanh of coherence; see methods). Vertical line at time 0 indicates nosepoke-on. White bar at top of each plot shows the distribution of end sampling times for each session. neurons and their connections and interactions that give rise to these oscillations do cause and are affected by oscillations. The problem of inferring these properties by measuring the LFP is a difficult one. These inferences cannot be made without converging experiments at many levels: intracellular recordings, recording of spiking properties in various behavioral states (awake, anesthetized, during odor discrimination, etc.), current source density, and pharmacological manipulation to name a few. When these studies are done, the LFP can be a powerful tool. In the case of gamma oscillations, many converging studies have shown that increases in gamma power represent better coordination of spikes among mitral/tufted cells.

Local Field Potentials: Interaction with the Extracellular Medium

Claude Bédard¹ and Alain Destexhe²

²Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

The local field potential (LFP) is the electric potential in the extracellular space around neurons. The LFP is generated by electric currents and charges, and is also interacting in several possible ways with the extracellular medium, such as capacitive interactions, polarization, or through ionic diffusion. These types of interaction confer specific frequency dependence of the extracellular electric potential and thus are important for correctly interpreting the LFP, as well as estimating the underlying neuronal sources (inverse problem).

Detailed Description

Introduction

In contrast to the electroencephalogram (EEG) recorded at the surface of the scalp, the local field potential (LFP) is recorded by inserting microelectrodes into neural tissue and is recordable using a variety of electrode systems, such as metal or silicon electrodes, or glass micropipettes. Early studies established that action potentials have a limited participation to EEGs or LFPs (Bremer 1938, 1949; Eccles 1951; Klee et al. 1965; Creutzfeldt et al. 1966a, b). The current view is that EEG and LFPs are generated by synchronized synaptic currents arising on cortical neurons, possibly through the formation of dipoles (Nunez 1981; Niedermeyer and Lopes da Silva 1998). This view applies to

cerebral cortex, hippocampus, or any brain structure where neurons form dipoles arranged in parallel.

The fact that action potentials have little participation to the LFP indicates strong frequency-filtering properties of cortical tissue. High frequencies (greater than ≈ 100 Hz), such as that produced by action potentials, are subject to a severe attenuation and therefore are visible only for electrodes immediately adjacent to the recorded cell. On the other hand, low-frequency events, such as synaptic potentials, attenuate less with distance. These events can therefore propagate over large distances in extracellular space and be recordable as far as on the surface of the brain, where they can participate in the genesis of the EEG. This frequency-dependent behavior is also seen routinely in extracellular unit recordings: the amplitude of extracellularly recorded spikes is very sensitive to the position of the electrode, but slow events show much less sensitivity to electrode position. In contrast, action potentials are recorded only for the cell(s) immediately adjacent to the electrode and are therefore very sensitive to changes in electrode position. This property is fundamental because it allows resolving single units from extracellular recordings.

EEG or LFP measurements also display approximately $1/f$ frequency scaling in their power spectra at low frequencies (Bhattacharya and Petsche 2001; Bédard et al. 2006b; Novikov et al. 1997; Pritchard 1992; Dehghani et al. 2010). The origin of such $1/f$ “noise” is at present unclear. The $1/f$ spectra can result from self-organized critical phenomena (Jensen 1998), suggesting that neuronal activity may be working according to such states (Beggs and Plenz 2003). Alternatively, the $1/f$ scaling may be due to filtering properties of the currents through extracellular media (Bédard et al. 2006b). This conclusion was reached by noting that the global activity reconstructed from multisite unit recordings scales identically as the LFP if a “ $1/f$ filter” is assumed, and without the need to assume self-organized critical states in neural activity.

We review here possible physical bases for such frequency-filtering properties, from the interaction between electrical events (such as membrane currents) and the extracellular space around neurons.

The “Standard Model”

The simplest model for the LFP assumes that the extracellular medium is purely *resistive* or *Ohmic*, with no (or negligible) frequency dependence. In this case, one considers a set of punctual current sources embedded in a homogeneous conductive medium of conductivity σ . The extracellular potential due to a single punctual current source can be deduced simply as follows. Starting from Ohm’s law ($\vec{j} = \sigma \vec{E}$), combined with the law of current conservation ($\vec{j} = \frac{i}{4\pi r^2} \hat{r}$) in spherical symmetry around the source, and by integrating along a straight line from the source to a given point in extracellular space, the extracellular potential at some distance r from the source i is given by:

$$V(r) = \frac{1}{4\pi\sigma} \frac{i}{r}, \quad (1)$$

if we assume that the reference $V(\infty) = 0$. This relation can also be deduced directly from Maxwell-Gauss law ($\nabla \cdot \vec{D} = \rho$) within the quasistatic electric approximation in the electric limit (de Montigny and Rousseaux 2006) a priori. (Note that this “electric limit” quasistatic approximation assumes that the magnetic field is negligible compared to the electric field ($\vec{E} < v_{\text{phase}} \vec{B}$). The other quasistatic approximation (“magnetic limit”) considers that the electromagnetic induction is not negligible.) In the case of a set of n current sources i_j , the superposition principle applies and one can write:

$$V(r) = \frac{1}{4\pi\sigma} \sum_{j=1}^n \frac{i_j}{r_j}, \quad (2)$$

where r_j is the distance from the source i_j to the position r in extracellular space. This expression captures many effects such as dipoles or multipolar configurations (if the distance is large compared to the size of the source). Equation 2 is widely used to model extracellular potentials since early models (Rall and Shepherd 1968) to today’s models of extracellular activity (Protopapas et al. 1998; Destexhe 1998; Nunez

and Srinivasan 2005; Gold et al. 2006; Pettersen and Einevoll 2011).

Microscopic Model of Frequency Filtering

A first possible physical mechanism giving rise to frequency-filtering properties is the fact that the extracellular space around neurons is not homogeneous but is subject to strong variations in conductivity and permittivity. In cerebral cortex, the different cellular processes are densely packed (Peters et al. 1991), and the extracellular space consists of a mixture of membranes of very low conductivity and extracellular highly conductive fluids. To formalize this situation, however, the equations above cannot be used and one must restart from first principles, as done previously (Bédard et al. 2004). To do this, we will consider a “microscopic” model where the electric parameters are subject to spatial variations according to the type of medium (fluid, membranes).

Starting from Maxwell equations, $\nabla \cdot \vec{D} = \rho^f$ (Maxwell-Gauss law), and $\nabla \times \frac{\vec{B}}{\mu} = \vec{j} + \frac{\partial \vec{D}}{\partial t}$ (Ampere-Maxwell law), if we consider a medium with constant magnetic permeability, we obtain:

$$\begin{aligned} \nabla \cdot \vec{D} &= \rho^f \\ \nabla \cdot \vec{j}^f + \frac{\partial \rho^f}{\partial t} &= 0. \end{aligned} \quad (3)$$

where $\vec{D}$, $\vec{j}^f$, and ρ^f are respectively the electric displacement, the free-charge current density, and free-charge charge density in the medium surrounding the sources.

In a linear medium, the equations linking the electric field $\vec{E}$ with electric displacement $\vec{D}$ and with current density $\vec{j}^f$ are given by:

$$\vec{D}(\vec{x}, t) = \int_{-\infty}^{\infty} \varepsilon(\vec{x}, \tau) \vec{E}(\vec{x}, t - \tau) d\tau \quad (4)$$

and

$$\vec{j}(\vec{x}, t) = \int_{-\infty}^{\infty} \sigma(\vec{x}, \tau) \vec{E}(\vec{x}, t - \tau) d\tau. \quad (5)$$

In this model, the electric parameters σ and ε take their “microscopic” values and are assumed to be independent of frequency. Indeed, the electric parameters of the extracellular fluid can be considered constant for frequencies lower than 1000 Hz (Gabriel et al. 1996c). In this case, the Fourier transforms of the above equations are respectively $\vec{D}_\omega = \varepsilon_\omega \vec{E}_\omega = \varepsilon \vec{E}_\omega$ and $\vec{j}_\omega = \sigma_\omega \vec{E}_\omega = \sigma \vec{E}_\omega = \sigma_z \vec{E}_\omega$ (where $\omega = 2\pi f$, where f is the frequency). It is important to note that σ_ω is a real number in this microscopic model, but this is not necessarily the case in a macroscopic model (as in next section).

Given the limited precision of measurements, we can consider $\nabla \times \vec{E} \approx 0$ for frequencies smaller than 1000 Hz. Thus, we can assume that $\vec{E} = -\nabla V$ such that the complex Fourier transform of Eq. 3 can be written as:

$$\nabla \cdot (\varepsilon(\vec{x}) \nabla V_\omega) = -\rho_\omega^f$$

$$\nabla \cdot (\sigma(\vec{x}) \nabla V_\omega) = i\omega \rho_\omega^f$$

Consequently, we have:

$$\nabla \cdot ((\sigma + i\omega\varepsilon) \nabla V_\omega) = 0 \quad (6)$$

This is the main equation to calculate the LFP in nonhomogeneous media, as derived previously (Bédard et al. 2004). It is general enough to calculate the propagation of the extracellular potential in extracellular media which can have a complex or inhomogeneous structure, as well as frequency-dependent electric parameters.

Equation 6 reduces to Laplace equation ($\nabla^2 V_\omega = 0$) when the medium is homogeneous with respect to σ and ε . Thus, Eq. 6 can be seen as a generalization of Laplace equation for media where σ and ε are nonhomogeneous. Except for particular cases where the ratio ε/σ is independent of position, Eq. 6 shows that, in nonhomogeneous media, the extracellular potential will necessarily have a different power spectral structure compared to that of the current sources, because the extracellular potential must be solution of a differential equation with frequency-dependent

coefficients. (Note that in this case, the electric potential does not satisfy Laplace equation ($\nabla^2 V_\omega = 0$), but obeys $\nabla \cdot \sigma(\vec{x}) \nabla V_\omega = 0$ when $\frac{\varepsilon}{\sigma}$ is constant everywhere.)

This “microscopic” model was simulated with different spatial profiles of conductivity and permittivity around neurons (Bédard et al. 2004). It was found that according to the profile of σ and ε , one can have a high-pass or low-pass filter, but in general, when σ is high at short distances and decays with larger distances, a low-pass filter is observed. For example, with an exponentially decaying conductivity, a low-pass filter attenuates more strongly the fast frequencies compared to low frequencies. A simulation of the LFP generated showed that the extracellular waveform of an action potential changes as the distance to the source is increased (Bédard et al. 2004). Thus, this model accounts for basic features of frequency filtering.

In this type of model, one can show that the electric potential is given by:

$$V_\omega = \frac{I_\omega^f}{4\pi\sigma(R)} \int_R^\infty \frac{1}{r'^2} \cdot \frac{\sigma(R) + i\omega\varepsilon(R)}{\sigma(r') + i\omega\varepsilon(r')} dr' \quad (7)$$

for a spherical is potential source embedded in any given medium. Here, I_ω^f is the free-charge current (in Fourier space). Note that the membrane current is the sum of the free-charge current (ion channels) and the capacitive current. Thus, the free-charge current is:

$$I_\omega^f = I_m(\omega) \frac{\sigma(R)}{\sigma(R) + i\omega\varepsilon(R)}$$

where I_m is the membrane current of the source, $\sigma(R)$ is the electrical conductivity, and $\varepsilon(R)$ is the electrical permittivity of the membrane at the source. (This relation is obtained from $\vec{j}_\omega^f = \sigma_\omega \vec{E}_\omega$ and $\vec{j}_\omega^c = i\omega\varepsilon_\omega \vec{E}_\omega$, where $\vec{j}_\omega^c$ is the capacitive current density.) It follows that the PSD of the voltage varies as $I_m(\omega)/\omega^2$ for high frequencies, because in this case, V_ω becomes proportional to $I_m(\omega)/\omega$.

Mean-Field Models of Extracellular Space

In principle, it is sufficient to solve Eq. 6 in the extracellular medium to simulate the LFP in inhomogeneous media. However, if the extracellular medium has a complex spatial structure, it may be tedious to assign the space dependence of the electric parameters σ and ε . One way to solve this problem is to consider a macroscopic or mean-field approach at a larger scale, in which the electric parameters will be considered as constant in space, but are the result of a microscopic mixture of different media such as fluids and membranes.

Note that Maxwell equations are invariant under change of scale if electric parameters are renormalized appropriately (see details in Jackson 1999; Bédard and Destexhe 2011). This approach is further justified by the fact that the values measured experimentally are averaged values, which precision depends on the measurement technique. Ideally, one should have a formalism that can integrate such macroscopic measurements. Thus, we need to design a macroscopic model, in which we take spatial averages of Eq. 6, and make a continuous approximation for the spatial variations of these average values. Such a mean-field model was proposed previously (Bédard and Destexhe 2009, 2011, 2014) and is detailed below.

To this end, we define macroscopic electric parameters, ε^M and σ^M , by taking an average of the “microscopic” electric parameters over some volume V :

$$\varepsilon_\omega^M(\vec{x}) = \langle \varepsilon_\omega(\vec{x}) \rangle_V = f(\vec{x}, \omega)$$

and

$$\sigma_\omega^M(\vec{x}) = \langle \sigma_\omega(\vec{x}) \rangle_V = g(\vec{x}, \omega).$$

We assume that V is of the order of $10^3 \mu m^3$ and is thus much smaller than the cortical volume, so that the mean values will be dependent of the position in cortex.

Because the average values of electric parameters are statistically independent of the mean value of the electric field, the density of

generalized current $\vec{j}^g$ is expressed as (The generalized current must be used in a medium where charge accumulation can occur, because in this case, the free-charge current is not conserved in neurons (Bédard and Destexhe 2013). Note that we assume that there is no charge creation (such as chemical reactions, ionization, etc.)).):

$$\begin{aligned} \langle \vec{j}^g \rangle_{|V}(\vec{x}, t) &= \int_{-\infty}^{\infty} \sigma^M(\tau) \langle \vec{E} \rangle_{|V}(\vec{x}, t - \tau) d\tau \\ &+ \int_{-\infty}^{\infty} \varepsilon^M(\tau) \frac{\partial \langle \vec{E} \rangle_{|V}}{\partial t}(\vec{x}, t - \tau) d\tau, \end{aligned}$$

where the first term in the right hand represents the “dissipative” contribution, and the term represents the “reactive” contribution (reaction from the medium, such as polarization). Here, all physical effects, such as diffusion, resistive, and capacitive phenomena, are integrated into the frequency dependence of σ^M and ε^M . The second term translates the fact that there is an inertia time for polarization (also called Maxwell-Wagner time), because the charges do not move instantaneously. This implies that the electric field will take a characteristic time to settle; this time is given by the Maxwell-Wagner time of the region in which the average is taken (see details in Planck and Brose 1932 and for application to biological membranes, see Bédard et al. 2006a).

The complex Fourier transform of $\langle \vec{j}^g \rangle_{|V}(\vec{x}, t)$ then becomes:

$$\begin{aligned} \langle \vec{j}^g \rangle_{|V} &= (\sigma_{\omega}^M + i\omega\varepsilon_{\omega}^M) \langle \vec{E}_{\omega} \rangle_{|V} \\ &= \gamma_{\omega}^M \langle \vec{E}_{\omega} \rangle_{|V}, \end{aligned} \quad (8)$$

where γ_{ω}^M is the complex macroscopic admittance.

Because $\gamma_{\omega}^M = (\sigma_{\omega}^M + i\omega\varepsilon_{\omega}^M)$ and $\langle \vec{E}_{\omega} \rangle = -\nabla(V_{\omega})$, the expressions above (Eq. 6) can also be written in the form:

$$\nabla \cdot (\gamma_{\omega}^M \nabla \langle V_{\omega} \rangle_{|V}) = 0. \quad (9)$$

by using the conservation of the generalized current.

We note that starting from the continuum model (Bédard et al. 2004), where only spatial variations were considered, and generalizing this model by including frequency-dependent electric parameters, gives the same mathematical form as the original model (compare with Eq. 6; see details in Bédard and Destexhe 2011). This form invariance will allow us to introduce different phenomena, such as surface polarization or ionic diffusion, by including an ad hoc frequency dependence in σ_{ω}^M and ε_{ω}^M . The physical causes of this macroscopic frequency dependence is that the cortical medium is microscopically non-neutral (although the cortical tissue is macroscopically neutral). Such a local non-neutrality was already postulated in a previous model of surface polarization (Bédard et al. 2006a). This situation cannot be accounted by Eq. 6 if σ_{ω}^M and ε_{ω}^M are frequency independent (in which case $\rho_{\omega} = 0$ when $\nabla V_{\omega} = 0$). Thus, including the frequency dependence of these parameters enables the model to capture a much broader range of physical phenomena.

Finally, a fundamental point is that the frequency dependences of the electrical parameters $\sigma_{\omega}^M = \text{Re}(\sigma_{\omega}^M) + i\text{Im}(\sigma_{\omega}^M)$ and $\varepsilon_{\omega}^M = \text{Re}(\varepsilon_{\omega}^M) + i\text{Im}(\varepsilon_{\omega}^M)$ cannot take arbitrary values but are related to each other by the Kramers-Kronig relations which are equivalent to a Hilbert transform (see Kronig 1926; Landau and Lifshitz 1981; Foster and Schwan 1989). It can be shown (Bédard and Destexhe 2018) that:

$$\begin{cases} \Delta \text{Im}(\gamma) = \mathcal{H}[\Delta \text{Re}(\gamma)] & (a) \\ \Delta \text{Re}(\gamma) = -\mathcal{H}[\Delta \text{Im}(\gamma)] & (b) \end{cases} \quad (10)$$

where $\gamma = \text{Re}(\gamma) + i\text{Im}(\gamma)$ and $\Delta\gamma = \gamma(\omega) - \gamma(\infty)$, and $\mathcal{H}$ is the Hilbert transform. $\text{Re}(\gamma)$ and $\text{Im}(\gamma)$ are respectively the real and imaginary part of the admittance γ (for more details, see Bédard and Destexhe 2018).

Note that these equations are valid for any linear medium (i.e., when Eqs. 4 and 5 are linear).

These relations will turn out to be critical to relate models to experiments, as shown previously (Jackson 1999; Bédard and Destexhe 2018).

Conclusions

In this entry, we have overviewed three formalisms to model LFPs. The first formalism, mostly based on Coulomb's law, expresses the potential as resulting from a set of current sources in a homogeneous resistive medium. This simple model is the one used by the majority of studies to simulate the LFP. It is justified by measurements suggesting that the extracellular medium is resistive (Logothetis et al. 2007; Miceli et al. 2017). However, it does not account for other measurements suggesting that the extracellular medium is non-ohmic (Gabriel et al. 1996b; Bédard et al. 2010; Dehghani et al. 2010; Gomes et al. 2016). There is also at present no convincing simulation of the spatial aspect of LFPs and why the spikes from only a few neurons are visible in extracellular recordings. This is why we need to consider other formalisms that allows one to include nonohmic aspects of the extracellular space, such as ionic diffusion or capacitive effects.

A first possibility is to explicitly integrate the strong inhomogeneity of extracellular media, in which the electric parameters σ and ϵ are strongly dependent on position. In this “microscopic” model, one must return to Maxwell equations to derive the correct equations to calculate the extracellular potential. The reason is that in such media, there will be charge accumulation, and the local free-charge conservation law $(\nabla \cdot \vec{j}^f = 0)$ does not apply (one must take into account the displacement current $\nabla \cdot (\nabla \times \vec{H}) = \nabla \cdot \left(\vec{j}^f + \frac{\partial \vec{D}}{\partial t} \right) = \nabla \cdot \vec{j}^f + \frac{\partial \rho}{\partial t}$ (see Bédard et al. 2004). This formalism was derived previously and was shown to simulate the low-pass filtering properties of extracellular space (Bédard et al. 2004). However, this “microscopic” formalism cannot integrate “macroscopic” measurements of σ and ϵ (Gabriel et al. 1996b) nor the

fact that the frequency filter deduced from experimental measurements is of $1/f$ type (Bédard et al. 2006b, 2010).

Thus, another formalism should be derived to include these more global aspects. We derived a “macroscopic” formalism using a mean-field derivation of Maxwell equations. This macroscopic formalism describes the tissue at a larger coarse-graining, and in which the electric parameters will be considered as spatial averages, and independent of position. They are the result of a mixture of different media such as fluids and membranes (Bédard and Destexhe 2009, 2011a, 2014). This mean-field formalism can directly integrate the macroscopic measurements of σ and ϵ , as well as macroscopic impedance measurements (Gomes et al. 2016). Thus, it can be used to simulate a wide variety of physical mechanisms in the extracellular medium. For example, it can be used to simulate the polarization phenomena that the electric field induces on neuronal membranes; it can also be used to integrate capacitive effects or the effect of ionic diffusion in the extracellular space.

This approach was possible because of the scale invariance of the mathematical structure of Maxwell equations. This property allows one to renormalize the electromagnetic parameters such that, even if the microscopic parameters do not depend on frequency, the macroscopic parameters can be frequency dependent in some media (see details in Bédard and Destexhe 2011). This is a consequence of the fact that the Maxwell-Wagner time is non-negligible in such media. Note that the standard model postulates that there is no such frequency dependence, which amounts to neglect the Maxwell-Wagner time and consider that the charges move infinitely fast, which corresponds to the simplest possible model in electromagnetism theory.

Using such formalisms, it was shown that ionic diffusion gives macroscopic electric parameters σ_ω^M and ϵ_ω^M displaying a frequency dependence as $1/\sqrt{\omega}$, which gives a $1/f$ filter in power spectra. Such a $1/f$ filter is consistent with experimental measurements, to relate LFPs with extracellularly recorded units (Bédard et al. 2006b) or LFPs with intracellular recordings (Bédard et al. 2010). It is also consistent with

conductivity measurements showing resistive media (Logothetis et al. 2007), because these measurements were designed to specifically avoid ionic diffusion (see discussion in Logothetis et al. 2007). Thus, if ionic diffusion has dominant effects, and if other effects such as inhomogeneities and polarization are negligible, then all measurements can be reconciled.

Thus, one can conclude that a neuron embedded in a non-resistive medium dominated by ionic diffusion is at present the only possible physical model that can account for all measurements done to date (reviewed in Bedard et al. 2017). A macroscopic model of LFPs (such as Eq. 9) is the most appropriate formalism to model ionic diffusion and was shown to reproduce the frequency-scaling properties of LFPs quantitatively (Bédard and Destexhe 2009). This model is general and includes the standard (resistive) model as a special case.

Finally, it is important to note that capturing the correct frequency dependence of the electric parameters is very important in the so-called “inverse problem” of estimating neuronal sources from measurements of extracellular voltage, such as the current-source density method (Mitzdorf 1985; Nicholson and Freeman 1975). It is evident that such a frequency-dependence, if present, will distort the extracellular electric potential; inversely, starting from the electric potential, the estimation of the source will be different if the frequency dependence is neglected (as in the classic CSD analysis). This problem was addressed recently, and it was shown that generalizing the CSD analysis to frequency-dependent media may lead to large differences in the mathematical estimates of neuronal sources (Bédard and Destexhe 2011).

In conclusion, we have shown that the expressions to calculate the extracellular potential from membrane currents are vastly dependent on the nature of the extracellular medium. If phenomena like inhomogeneities, capacitive effects, polarization or ionic diffusion are taken into account, the medium exerts a strong frequency filtering action on the propagation of the extracellular potentials. As a consequence, if such effects are confirmed, it is imperative to take them into account to correctly

model the extracellular potentials. Similarly, estimating neuronal sources from extracellular measurements also requires to know precisely the nature of the frequency filtering properties of the medium. So far, measurements are contradictory (Gabriel et al. 1996a, b, c; Logothetis et al. 2007; Gomes et al. 2016; Miceli et al. 2017; Bédard and Destexhe 2017). In a recent review paper (Bedard et al. 2017), we overviewed different possible causes for these contradictory measurements and outlined new experiments that should be done to settle the issue.

Definition

The local field potential (LFP) is the electric potential in the extracellular medium around neurons. The LFP is a signal available in many recording configurations, ranging from single-electrode recordings to multi-electrode arrays. The LFP has specific spatial and temporal properties, and also depends on brain state. Different classes of models are used to model the LFP.

Introduction

The local field potential (LFP) is the electric potential in the extracellular space around

neurons, and can be recorded using different types of micro-electrodes (metal, silicon, or glass micropipettes). Its characteristics differ from the electroencephalogram (EEG), which is recorded at the surface of the scalp with macro-electrodes. It was shown that the LFP samples relatively localized populations of neurons, as these signals can be very different for electrodes separated by 1 mm (Destexhe et al. 1999) or even by a few hundred microns (Katzner et al. 2009). In contrast, it is thought that the EEG samples large populations of neurons, spanning up to several centimeters (Niedermeyer and Lopes da Silva 1998). Besides these differences, EEG and LFP signals display the same type of oscillations during wake and sleep states (Steriade 2003). These different properties are reviewed here.

Spatial and Temporal Properties of LFPs

In Fig. 1a, human LFP recordings are shown using a very popular extracellular multi-electrode array system, called the “Utah array,” developed at the University of Utah and by BlackRock Microsystems. This 100-electrode array was implanted in human medial temporal cortex together with surface electrodes (Fig. 1b). The surface electrodes record the electrocorticogram (EcoG in Fig. 1), the electric potential at the surface of the cortex (green signals in Fig. 1c). By contrast, the LFP provides a recording of the electric potential from within the brain tissue (black signals in Fig. 1c). In this example, recorded during slow-wave sleep, one can clearly see slow delta waves in both the surface EcoG and depth LFP recordings. A number of discriminated units are also shown and were recorded using the same set of electrodes.

We next illustrate the state-dependence of the LFP signal using LFPs recorded in cat parietal cortex during wake and sleep states (Fig. 2). This figure shows that the LFP displays the same features as classically seen from the EEG: during wakefulness, the LFP was dominated by low-amplitude fast oscillations (Fig. 2a), while during slow-wave sleep, the LFP displayed high-amplitude slow waves (Fig. 2b). During rapid-eye movement (REM) sleep (Fig. 2c), the LFP

(b) Plan of implantation of surface electrodes (black dots). Inset: magnified view of the medial temporal lobe, with four surface electrodes (green) and the Utah array (gray square). (c) Recordings obtained with the different electrode systems,

surface electrodes (EcoG, green), local field potentials (LFP), and identified neurons (Units; red = inhibitory, blue = excitatory). The four nearby surface EcoGs are shown (green), while four randomly chosen LFPs were shown among the 100 electrodes available. This example was recorded during slow-wave sleep, and one can see slow delta waves in the surface EcoG and in the LFPs, as well as in the modulation of the firing of units. (Modified from Peyrache et al. 2012; Destexhe and Bedard 2013)

showed nearly identical characteristics as during wakefulness. It was shown that the high similarity between Wake and REM states extends to about everything that can be measured electrophysiologically, such as the spectral content, the correlation dynamics, and the unit activity (Destexhe et al. 1999). On the other hand, slow-wave activity is clearly different, as shown for example by their different pattern of coherence as a function of distance compared to the low coherence of fast activity during Wake and REM states. This difference can be quantified by calculating spatial correlations, and in particular their decay with

distance. As expected from the LFP signals, the correlations remained high for larger distances only during slow-wave sleep (Fig. 2, middle panels). In contrast, the temporal correlations displayed similar profiles between different brain states (Fig. 2, right panels).

Relation Between LFP and Neuronal Activity

Figure 3 illustrates that the relationship between LFP and the firing of neurons highly depends on

Local Field Potentials: LFP, Fig. 2 Local field potential recordings in cat parietal cortex during wake and sleep states. Eight bipolar tungsten electrodes (inter-electrode distance of 1 mm) were inserted into the depth (1 mm) of areas 5–7 of cat parietal cortex (suprasylvian gyrus, area 5–7; see top scheme for arrangement of electrodes). Local field potentials (LFPs) are shown (left panels) together with a representation of the correlations as a function of distance (Spatial correlations; middle panels) and time (Temporal correlations; right panels). (a) When the animal

was awake, LFPs were characterized by low-amplitude fast activities in the beta/gamma frequency range (15–75 Hz). Correlations decayed steeply with distance and time. (b) During slow-wave sleep, the LFPs were dominated by large-amplitude slow-wave complexes recurring at a low frequency (<1 Hz; up to 4 Hz). Correlations stayed high for large distances. (c) During episodes of REM sleep, LFPs and correlations had similar characteristics as during wake periods (* indicates a PGO wave). (Modified from Destexhe et al. 1999)

the brain state. During wakefulness, the low-amplitude fast-frequency LFP was associated with sustained irregular firing activity in the units (Fig. 3a, b, Wake). There was no apparent relation between units and LFP by visual

inspection. However, a statistical analysis revealed that the depth-negative deflections were on average related to an increase of firing activity in the units (Fig. 3c, Wake; see details in Destexhe et al. 1999). During slow-wave sleep, the

Local Field Potentials: LFP, Fig. 3 (continued)

ensemble activity tended to be more bursty (Fig. 3a, SWS). At closer scrutiny (Fig. 3b), it appears that synchronous “silences” in all the units occur systematically and simultaneously with the depth-positive part of the slow wave (Fig. 3b, SWS; blue shaded area). This type of synchronized silence is often referred as “Down-state,” and was also visible in the human recordings (see Fig. 1c). This modulation of firing by the slow wave also appears in the statistical relation between units and slow waves (Fig. 3c, SWS). This relation between slow waves and Up and Down states in single neurons was demonstrated using intracellular recordings in natural slow-wave sleep in cats (Steriade et al. 2001; reviewed in Steriade 2003). We therefore conclude that the human and cat recordings display very similar features of the relation between LFPs and neuronal units.

In a more recent study in human and monkey (Telenczuk et al. 2017), it was shown that the LFP is more tightly related to inhibitory activity. This conclusion was reached by analyzing datasets where excitatory and inhibitory cells could be distinguished, and the relation could be determined separately. In particular, the so-called unitary LFP (uLFP) results from the synchronous release of synapses belonging to a single axon. The uLFP of inhibitory cells is much more powerful than that of excitatory cells (Telenczuk et al. 2017), a conclusion also reached by detailed computational models (Telenczuk et al. 2020a). uLFPs can constitute the basis of a “kernel method” to calculate LFPs from point neurons (see details in Telenczuk et al. 2020b; see also the *Modeling LFPs* section below).

Power Spectra and Frequency Scaling of LFPs

Another characteristic of EEG and LFP signals is that their power-spectrum exhibits $1/f$ frequency scaling at low frequencies, as shown by a number of studies (Pritchard 1992; Novikov et al. 1997; Bhattacharya and Petsche 2001; Bedard et al. 2006a; Dehghani et al. 2010). Figure 4 illustrates such scaling in the human EEG and in the LFP recorded with tungsten electrodes in cat parietal cortex, both when the subject was awake and attentive. In these conditions, the low-frequency end of the PSD scales as $1/f$. A more detailed study showed that the scaling exponent of the EEG signals varies from 1 to 2 according to the brain region considered (Dehghani et al. 2010).

Such $1/f$ “noise” may have different origins. First, $1/f$ spectra can result from self-organized critical phenomena (Jensen 1998), suggesting that neuronal activity may be working according to such states (Beggs and Plenz 2003), but this subject is controverted (Bedard et al. 2006a; Dehghani et al. 2012). The morphology of the neuron may also be responsible for filtering in the $1/f$ to $1/f^2$ range (Pettersen and Einevoll 2008), but this scaling applies only to high frequencies and does not explain the $1/f$ scaling at low frequencies. Finally, the $1/f$ scaling may be due to filtering properties of the currents through extracellular media (Bedard et al. 2006a). This conclusion was reached by noting that the global activity reconstructed from multisite unit recordings does not reproduce the power spectra found for LFPs (Fig. 5). This failure to reconstruct LFPs spectra from unit activity applies in particular to the $1/f$ scaling at low frequencies. Interestingly, a $1/f$ component was miss-

Local Field Potentials: LFP, Fig. 3 Relation between LFP and unit activity in different brain states. (a) *Left*: During wakefulness, the low-amplitude fast-frequency LFP activity is associated with highly irregular firing activity of the 8 multi-units recorded simultaneously (same experimental setup as in Fig. 2). *Right*: During slow-wave sleep (SWS), the activity is similar as wakefulness, except that synchronized “silences” of firing activity occur in all cells simultaneously, and in relation to the slow waves. (b) Same activity as in A at 20 times higher

temporal resolution. The blue shaded area indicates the synchronized silence (“Down state”) simultaneous in all cells, and occurring in parallel with slow waves. (c) Wave-triggered averages of spiking activity. During wakefulness, the LFP negative peaks were correlated with an increased firing activity in the units. During SWS, the negative peak of the slow wave was correlated with a strong decrease of firing in the units (Down state), followed by a rebound a sustained activity (Up state). (Modified from Destexhe et al. 1999)

Local Field Potentials: LFP, Fig. 4 $1/f$ scaling of EEG and LFP signals. The top traces show examples of human EEG recordings (left, vertex EEG) and LFP recording from cat parietal cortex (right) during awake and attentive states. The corresponding power spectra (lower panels) display approximate $1/f$ scaling at low frequencies. The straight

lines (red) indicate a slope of -1 in this log-log representation. The signals were not filtered, except for a notch filter at 60 Hz (*) for the EEG, and the data acquisition filters at high frequencies (not visible at this scale). (Modified from Bedard and Destexhe 2012)

ing for all frequency bands (compare Fig. 5b and d), suggesting that a “ $1/f$ filter” could explain the LFP spectra, without the need to assume self-organized critical states in neural activity (Bedard et al. 2006a). We will see below that ionic diffusion may explain such a $1/f$ filter.

Modeling LFPs

In this section, we review different approaches that have been proposed to model LFPs (see also the chapter by Bedard and Destexhe, ► “Local Field Potentials: Interaction with the Extracellular Medium” in this volume).

Standard model: The first model that was proposed for the genesis of LFPs, which we call here the “standard model,” assumes that the LFP is generated by a set of current sources in a homogeneous and resistive extracellular

medium. According to this model, the extracellular potential V at a position r in extracellular space resulting from a set of n current sources i_j is given by:

$$V(r) = \frac{1}{4\pi\sigma} \sum_{j=1}^n \frac{i_j}{r_j}, \quad (1)$$

where σ is the electric conductivity, r_j is the distance from the source i_j to the position r in extracellular space. Equation 1 is widely used to model extracellular potentials, since early models (Rall and Shepherd 1968) to today’s models of LFPs (Protopapas et al. 1998; Destexhe 1998; Nunez and Srinivasan 2005; Gold et al. 2006; Pettersen and Einevoll 2008).

General model: A more general model of the LFP must explicitly consider the inhomogeneities of conductivity in the extracellular space around neurons. In such a case, one cannot use the

Local Field Potentials: LFP, Fig. 5 Failure to reconstruct LFP power spectra from unit activity. (a) LFP recording in awake cat parietal cortex (same recording as in Fig. 4, left). (b) Power spectral density (PSD) of the LFP, showing two scaling regions, $1/f$ at low frequencies (red line, slope = -1), and $1/f^3$ at high frequencies (blue line; slope = -3). (c) Unit activity from the same experiment.

(d) Attempt to reconstruct the LFP signal from the unit activity. The low-frequency end of the PSD was constant (zero slope), while the high-frequency end scaled as $1/f^2$ (blue line, slope = -2). An exponent of -1 is missing to reproduce the LFP scaling. (Modified from Bedard et al. 2006a)

equation above, and must start from first principles (Maxwell equations) and derive the equations that govern the extracellular potential V . This was done previously (Bedard et al. 2004), and the main result is that, in a non-homogeneous medium, the extracellular potential obeys the following equation (written in Fourier space):

$$\nabla \cdot ((\sigma + i\omega\epsilon)\nabla V_\omega) = 0. \quad (2)$$

This equation gives the evolution of the ω -frequency component of the extracellular potential, V_ω , as a function of the electric conductivity σ and permittivity ϵ , which are both allowed to vary in space. This equation is general enough to calculate the propagation of the extracellular potential in

extracellular media which can have a complex or inhomogeneous structure. If σ and ϵ are constant, this model recovers the standard model, and is therefore a generalization of this model. This approach was used to show that inhomogeneities of conductivity can lead to a low-pass filtering of the extracellular medium, which generates more realistic patterns of extracellular potentials (Bedard et al. 2004) and CSD profiles (Bazhenov et al. 2011).

Mean-field model: A third type of model considers the LFP as generated at more macroscopic scales. In this case, the same approach as above is followed but using a mean-field formalism (Bedard and Destexhe 2009, 2011). Instead of considering that σ and ϵ vary in space, one defines

macroscopic electric parameters, ϵ^M and σ^M , by taking an average of the “microscopic” electric parameters over some volume Vol :

$$\epsilon_{\omega}^M(\vec{x}) = \langle \epsilon_{\omega}(\vec{x}) \rangle_{|Vol}$$

and

$$\sigma_{\omega}^M(\vec{x}) = \langle \sigma_{\omega}(\vec{x}) \rangle_{|Vol}.$$

It must be emphasized that these macroscopic electric parameters are in general frequency dependent. This frequency dependence arises from the renormalization process, and is necessary for the macroscopic equations to be consistent. It can be shown that different physical processes will result in different frequency dependence of these parameters. A perfectly resistive and homogeneous medium will result in no frequency dependence of σ^M and ϵ^M , while processes such as polarization, capacitive effects, and ionic diffusion will all lead to specific frequency-dependent profiles of σ^M and ϵ^M . For example, for a diffusive medium we have $\sigma^M + i\epsilon^M = k\sqrt{\omega}$ (where k is a complex number; see details in Bedard and Destexhe 2009).

Defining similarly a macroscopic extracellular potential $\langle V_{\omega} \rangle_{|Vol}$ by averaging V_{ω} over a volume Vol leads to the following mean-field equation for V :

$$\nabla \cdot ((\sigma_{\omega}^M + i\omega\epsilon_{\omega}^M)\nabla \langle V_{\omega} \rangle_{|Vol}) = 0. \quad (3)$$

This equation generalizes Eqs. 1 and 2 at macroscopic scales. Solving this equation will give access to the macroscopic variations of V .

Kernel model: Finally, a more recent approach has been proposed where the LFP is generated using a “kernel method” (Telenczuk et al. 2020b). In this model, the LFP is calculated from the sole knowledge of the spiking activity of neurons. The spiking activity is convolved with kernels specific to each neuron type:

$$V(r) = \sum_k K_e(r, t - t_{e,k}) + \sum_l K_i(r, t - t_{i,l}), \quad (4)$$

where $K_e(r, t - \tau)$ are $K_i(r, t - \tau)$ the excitatory and inhibitory uLFP kernels, while $\{t_{e,k}\}$ and $\{t_{i,l}\}$ are the spike times of excitatory and inhibitory neurons, respectively.

The kernels typically have the form:

$$K(r, t) = A(r) \Theta(t) \exp \left[-(t - t_p)^2 / 2\sigma^2 \right], \quad (5)$$

where A is an amplitude constant (which can be negative), Θ is the Heaviside step function, σ is the standard deviation in time, and t_p is the peak time of the kernel. The latter is given by

$$t_p = t_0 + d + |r - r_0| / v_a, \quad (6)$$

where t_0 is the time of the spike of the cell, $|r - r_0|$ is the distance between cell and electrode, d is a constant delay, and v_a is the axonal speed.

This method was tested on various neural networks using kernels estimated from human microelectrode recordings, and it was shown that the kernel LFP provides a low-pass version of the LFP calculated with the standard model (see details in Telenczuk et al. 2020b).

Reconstructing the Spectral Structure of LFPs from Unit Activity

To reconstruct the correct frequency-scaling properties of LFPs, as measured experimentally (Fig. 5b), we showed above that the standard model was unable to account for this frequency scaling (Fig. 5d). To determine if the non-resistive properties of the extracellular medium can lead to the correct scaling behavior, one can use the mean-field LFP model described above. Using Eq. 3 with $\sigma^M + i\epsilon^M = k\sqrt{\omega}$ derived from extracellular ionic diffusion (Bedard and Destexhe 2009), it was possible to reconstruct LFPs with frequency scaling in qualitative agreement with experimental data (Fig. 6). With ionic diffusion, it is therefore possible to reconstruct the correct frequency scaling properties of LFPs from unit activity, for all frequencies, which is presently not possible with any other model. Ionic diffusion

Local Field Potentials: LFP, Fig. 6 Successful reconstruction of LFP power spectra from unit activity when ionic diffusion is taken into account. The PSD of the LFP was reconstructed from the units (inset; same as in Fig. 5c),

taking into account ionic diffusion. The reconstructed LFP displays the same frequency scaling as the real LFP (compare with Fig. 5b). (Modified from Bedard and Destexhe 2009)

appears, therefore, as a plausible physical mechanism to fully explain the spectral structure of LFPs (Bedard and Destexhe 2009).

Conclusions

In this contribution, we have illustrated the main spatial and temporal (or frequency) properties of LFPs. It is important to emphasize that spatial (correlations with distance) and temporal properties (frequency scaling, frequency content) of LFPs are highly dependent on brain state. In the awake brain, the LFPs scales as $1/f$ at low frequencies, a property which was also found at the level of the EEG (Pritchard 1992; Novikov et al. 1997; Bhattacharya and Petsche 2001; Bedard et al. 2006a; Dehghani et al. 2010).

To model the LFP, a first type of approach, the simplest conceptually, postulates that the LFP is generated by a set of current sources embedded in a homogeneous and resistive medium. This approach leads to a very simple relation between the extracellular potential and the current sources

(Eq. 1). This formalism is used in the vast majority of studies modeling the LFP. It provides an acceptable simulation of the LFP in many cases (e.g., Rall and Shepherd 1968; Protopapas et al. 1998; Destexhe 1998; Holt and Koch 1999; Nunez and Srinivasan 2005; Gold et al. 2006; Milstein and Koch 2008; Pettersen and Einevoll 2008; Linden et al. 2011). The procedures to implement this standard model are now available in popular simulators such as NEURON, or python scripts such as LFPy (Linden et al. 2014) or NeuronEAP (Telenczuk and Telenczuk 2016).

Although resistive extracellular media are justified by some measurements (Logothetis et al. 2007; Miceli et al. 2017), other measurements suggest that the extracellular medium is non-ohmic (Gabriel et al. 1996; Bedard et al. 2010; Dehghani et al. 2010; Wagner et al. 2014; Gomes et al. 2016). But most importantly, the microstructure of extracellular space shows that it is far from being uniform, and rather consists of an aggregate of highly conductive fluids with low-conductive and capacitive membranes. There is therefore a serious possibility that the medium is more

complex than a simple resistor, although this issue is still unclear today.

To account for such inhomogeneities, a specific formalism must be derived, starting from Maxwell equations and integrate electric parameters that depend on the spatial position in extracellular space. Such a formalism revealed that the inhomogeneities of conductivity can give rise to strong filtering properties of LFPs (Bedard et al. 2004). Such a model should be used if one needs to account in detail for the attenuation of LFPs with distance. It was also shown that this model accounts for the characteristics of the current-source density (CSD) analysis of the slow oscillation in cerebral cortex (Bazhenov et al. 2011). A caveat of this model is that it is complex to apply in principle, because it requires to know in detail the 3D arrangement of fluids and membranes in the extracellular space around each neuron.

Another formalism, easier to implement in practice, is a mean-field approach that describes the tissue at a larger coarse-graining. In this case, the extracellular potential is considered as an average over some volume of space. This mean-field model of LFPs (Bedard and Destexhe 2009, 2011) also presents the advantage that it can directly incorporate macroscopic measurements of σ and ϵ in brain tissue (Gabriel et al. 1996; Gomes et al. 2016). This approach can integrate various physical mechanisms, such as the polarization of the extracellular medium (Bedard et al. 2006b) or ionic diffusion (Bedard and Destexhe 2009). Ionic diffusion turns out to be the mechanism that best explains various measurements including the $1/f$ scaling properties of LFPs at low frequencies (Fig. 6). This mean-field approach can also be applied to generalize the CSD analysis (which is only valid in resistive media) to extracellular media with arbitrarily complex electrical properties (Bedard and Destexhe 2011).

Finally, a recent approach, more phenomenological, consists of reconstructing the LFP from kernels estimated from the relation between units and LFPs extracted from experimental data (Telenczuk et al. 2020b). This method has the advantage of simplicity, because it only requires the knowledge of the spike times of neurons,

while biophysical models require all membrane currents, which is considerably more complex. The kernel method is also very fast to compute in comparison to biophysical models. The kernel LFP method was shown to provide good estimates of surface and depth LFPs from networks of spiking neurons (Telenczuk et al. 2020b). NEURON and python scripts have been published to use the kernel-based method (Telenczuk et al. 2020c). Interestingly, the kernel LFP appears as a low-pass version of the LFP generated by the standard model, which may also indicate low-pass filtering properties of the extracellular medium. This relation should be investigated in future studies.

Locomotor Pattern Generation in the Rodent Spinal Cord

Ronald Harris-Warrick
Department of Neurobiology and Behavior,
Cornell University, Ithaca, NY, USA

Synonyms

CPG; Locomotor central pattern generator; Spinal locomotor network

Definition

The locomotor central pattern generator is a neural network in the spinal cord that can generate the basic motor pattern for locomotion in the absence of sensory feedback or rhythmic input from the brain. Most research in rodents has focused on hind limb movements: the hind limb CPG is located in lower thoracic and lumbar segments of the spinal cord. This network generates both the locomotor rhythm (cycle frequency) and the detailed phasing of motoneuron activation during the cycle, including alternation of left and right limb movements and alternation of ipsilateral flexor and extensor activity.

Detailed Description

A central pattern generator (CPG) is a limited neural network that can produce an organized rhythmic motor output in the absence of sensory or descending inputs from other parts of the nervous system (Marder and Calabrese 1996). CPGs drive behaviors such as locomotion, respiration, mastication, and digestion (Gossard et al. 2010). The CPG for vertebrate locomotion is located in the spinal cord. This entry will focus on the organization of the rodent hind limb locomotor CPG, which directs rhythmic movements of the left and right hind limbs of rats and mice. Under normal circumstances, in the intact animal, locomotor CPGs are strongly affected by sensory feedback, which can, for example, determine the timing of the swing phase initiation during walking, by descending inputs from the brain, which normally provide tonic drive to activate the locomotor CPG, and by modulatory inputs which shape CPG output and prepare it for activation.

The rodent spinal cord is particularly useful for studies of CPG function because the locomotor CPG can be activated in the isolated spinal cord (Smith and Feldman 1987). Motor output is monitored with extracellular recordings of motoneuron activity from the ventral roots (VRs); higher lumbar VRs (L1–2) contain axons predominantly from flexor motoneurons (MNs), while lower lumbar VRs (L4–5) predominantly contain axons of extensor MNs (Fig. 1a). The CPG can be activated by a number of methods which non-specifically excite the isolated spinal cord. These include pharmacological manipulation (typically with a combination of *N*-methyl-d-aspartate (NMDA) and serotonin), sensory stimulation by tonic activation of dorsal roots, and tonic stimulation of the brainstem or specific activation of brainstem regions such as the parapyramidal region (Jordan 1998; Jordan et al. 2008). The elicited motor output shows alternation of left and right segmental VRs (e.g., left and right L2) combined with alternation of ipsilateral flexor (L2) and extensor (L5) MN activity (Fig. 1b). This is the fictive equivalent of walking.

Lesion studies have shown that the rodent CPG is distributed continuously along the lower

Locomotor Pattern Generation in the Rodent Spinal Cord, Fig. 1 Fictive locomotion in the isolated rodent spinal cord. (a) Experimental preparation, with extracellular recordings from the right and left L2 (flexor-dominated) and L5 (extensor-dominated) ventral roots of the lumbar spinal cord. Recordings from identified interneurons have been mostly performed in the rostral region.

(b) simultaneous extracellular recordings from left and right flexor (L2) and the left extensor (L5) ventral roots during fictive locomotion evoked by bath application of NMDA, serotonin (5-HT), and dopamine (DA). Alternation across the cord (IL2 and rL2) and between ipsilateral flexors and extensors (IL2 and IL5) are seen

thoracic and lumbar segments of the spinal cord (Kudo and Yamada 1987b; Kjaerulff and Kiehn 1996; Cowley and Schmidt 1997). Each segment, and even each hemisegment, is capable of generating a rhythmic output with appropriate MN phasing, showing that both the “clock,” or rhythm-generating component of the CPG, and the pattern-organizing network, which determines the phasing of MN activation, are widely and redundantly distributed over many spinal segments. Coordination of this distributed network requires ascending and descending interneuron coordinating pathways, which have not yet been identified in rodents.

Identified Interneurons in the Mouse Spinal Locomotor CPG

Recent studies of the developmental determination of spinal interneurons in mice have provided important tools to identify interneurons that may be components of the hind limb locomotor CPG (Stepien and Arber 2008; Goulding 2009; Gosgnach 2011; Kiehn 2011). These interneurons are identified by selective expression of defining transcription factors during development, which drives differentiation of the interneuron subtypes

from common precursors. Modern genetic techniques allow visualization of these neurons as well as manipulation of their activity and selective elimination. The major interneuron types implicated in locomotor CPG function are described below.

V0 Interneurons

This is a heterogeneous class of interneurons, defined by embryonic expression of *Dbx1*. Almost all of the V0 interneurons are commissural, sending their axons to synapse on neurons on the opposite side of the spinal cord. As expected, they play a role in left-right hind limb coordination. The V0 group has been subdivided into four subgroups based on subsequent transcription factor expression and location of origin (Gosgnach 2011; Kiehn 2011). All of these groups are rhythmically active during fictive locomotion in the neonatal mouse spinal cord, suggesting that they may participate in the locomotor CPG. V0_D interneurons comprise 70% of the V0 class; they are predominantly inhibitory, contralaterally projecting commissural interneurons (CINs). The V0_V class represents the majority of the remaining V0 neurons; they express *Evx1/2* and are excitatory glutamatergic CINs. The V0_C group (5% of the class) expresses *Evx1/2* and *Pitx2* and

generates cholinergic interneurons that have either commissural or ipsilaterally directed axons; these neurons are the source of the cholinergic C-boutons found on predominantly ipsilateral MNs (Zagoraïou et al. 2009). There is also a small group of $V0_G$ neurons which are glutamatergic, $V0_V$ -derived, Pitx2-positive neurons (Zagoraïou et al. 2009). Ablation of the $V0_V$, $V0_C$, and $V0_G$ groups in *Evx1* mutant mice did not affect fictive locomotion (Lanuza et al. 2004); selective loss of cholinergic function in the $V0_C$ group does not affect behavioral locomotion but may selectively reduce extensor muscle activity during swimming behavior (Zagoraïou et al. 2009). Ablation of the entire $V0$ population in *Dbx1* mutant mice leads to a disruption of left-right alternation, with drift between the two sides during neonatal fictive locomotion (Lanuza et al. 2004), and may enhance a hopping behavior in intact mice (Kiehn 2011). This emphasizes the major role of the commissural $V0$ interneurons in coordinating the networks on the left and right sides of the spinal cord.

V1 Interneurons

The $V1$ class is characterized by expression of *En1* and encodes ipsilaterally projecting inhibitory GABAergic/glycinergic interneurons. Only about 30% of these neurons have been physiologically characterized. Renshaw cells are detected by their selective expression of *En1* and calbindin. They are activated by motoneuron collateral axons and provide a negative feedback to inhibit the motoneurons that excite them. They are rhythmically active, in phase with either ipsilateral flexor or extensor motoneurons during fictive locomotion, and may help terminate MN activity in each cycle (Nishimaru et al. 2006). They receive rhythmic excitatory drive from MNs, which release both ACh and glutamate in the neonate (Nishimaru et al. 2005), and ipsilateral and contralateral rhythmic inhibition to shape their output. Another set of $V1$ neurons differentiates into Ia inhibitory interneurons; these are activated by muscle spindle afferents and monosynaptically inhibit antagonist muscles. Flexor- and extensor-related Ia inhibitory interneurons are mutually inhibitory. These neurons are

rhythmically active during the inhibitory phase of the antagonist MNs. Deletion or acute silencing of the entire $V1$ population causes a dramatic slowing of the motor pattern and prolongation of motoneuron firing during the cycle, with little effect on the motoneuron phasing (Gosgnach et al. 2006). This suggests that the $V1$ population has input to the rhythm-generating components of the locomotor CPG, though how this is effected is unknown; presumably this is one function of the 70% of $V1$ interneurons that are not yet identified.

V2 Interneurons

The $V2$ class is derived from progenitors that express *Lhx3* and contains several different subtypes. The $V2a$ class expresses *Chx10* and forms glutamatergic, excitatory ipsilaterally projecting interneurons. $V2a$ neurons have been shown to synapse onto *Evx1*-expressing $V0_V$ commissural interneurons and appear to play a role in regulation of left-right alternation (Crone et al. 2008). Some $V2a$ neurons also synapse onto ipsilateral motoneurons. Genetic deletion of $V2a$ interneurons has little motor phenotype at low locomotor frequencies, but as the frequency of walking increases, left-right alternation is much more variable than usual, and at high frequencies, a synchronous left-right bounding gait is observed which is never seen in control mice (Crone et al. 2008, 2009). A similar frequency-dependent effect is seen in the isolated spinal cord during fictive locomotion. $V2a$ interneurons are only weakly active at low frequencies but are increasingly active and recruited as the cycle frequency increases (Zhong et al. 2010). Thus, these neurons seem to play a major role to prevent a gait change to bounding at high cycle frequencies. Recent studies of the consequences of spontaneous motor deletions during fictive locomotion (described below) suggest that the $V2a$ interneurons can be split into two subgroups, one of which is related to the rhythm generator network in the CPG and drives CINs, while the other is an output path from the pattern formation networks of the CPG and provides some of the drive to ipsilateral motoneurons (Zhong et al. 2012). The $V2b$ class of interneurons expresses *GATA2/3* and forms ipsilaterally projecting inhibitory interneurons.

Little is known about this class, though it may form a small subset of the Ia inhibitory interneurons which are mostly generated from the V1 class (Kiehn 2011). A new class of V2c interneurons has recently been identified which are derived from the GATA3-expressing V2b lineage and express Sox1 (Panayi et al. 2010). At present, nothing is known of their roles in the locomotor CPG.

V3 Interneurons

The V3 class is derived from progenitors that express Sim1 (Zhang et al. 2008). These interneurons are excitatory and glutamatergic; most of them are commissural, though about 15% have ipsilateral axons. These neurons form synapses onto contralateral and ipsilateral motoneurons, Renshaw cells, and Ia interneurons. Selective silencing of V3 neurons caused a marked degeneration in the regularity of the fictive locomotor rhythm both in vivo and in the isolated neonatal spinal cord: there were marked variability in the duration of ventral root bursts and asymmetry in left and right bursting (Zhang et al. 2008). However, the basic rhythmic alternating motor pattern was conserved. Thus, V3 interneurons appear to be important in retaining the regularity of the motor rhythm, especially by coordinating left and right sides of the cord.

Hb9 Interneurons

The Hb9 transcription factor is predominantly expressed in motoneurons, but it is also expressed in a small set of interneurons located adjacent to the central canal in the ventral cord. These interneurons are rhythmically active during fictive locomotion and show endogenous oscillator activity when excited by NMDA and serotonin. This has led to suggestions that the Hb9 interneurons may be components of the rhythmogenic kernel of the locomotor CPG (Hinckley et al. 2005; Wilson et al. 2005; Brownstone and Wilson 2008; Brocard et al. 2010). However, during locomotor activity, their onset of firing lags behind that of ipsilateral motoneurons; during electrically stimulated fictive locomotion, they are only weakly active or silent after the first few cycles, despite continued strong rhythmic motoneuron

firing (Kwan et al. 2009). These results suggest that they may not be the sole rhythmic drive for locomotion, but they could participate in mediating the rhythm generator network's drive of lower-level interneurons and motoneurons.

dl6 Interneurons

This mixed class of commissural and ipsilaterally projecting interneurons arises from Lbx1-expressing progenitors in the dorsal embryonic spinal cord and migrates ventromedially to laminae VII/VIII, where the locomotor CPG is localized. Transmitter labeling suggests that these are a mixture of excitatory and inhibitory interneurons. They have been proposed to express Wt1 (Goulding 2009); an inhibitory subpopulation expresses Dmrt3 (Vallstedt and Kullander 2013), which may help identify them in future experiments. Physiological analysis of dl6 neurons (Dyck et al. 2012) showed that the majority are rhythmically active during fictive locomotion. Physiologically, they divide into two populations: one population possesses endogenous rhythmic capability, while the other fires rhythmically due to synaptic stimulation. Dyck et al. propose that the endogenously rhythmic neurons may be components of the rhythm-generating kernel of the CPG, along with other interneurons. Mutants lacking Dmrt3 show relatively normal fictive locomotion at low speeds but increasing lack of coordination both of left-right and ipsilateral flexor-extensor phasing at higher speeds; Vallstedt and Kullander (2013) propose that they may act as phase-lock neurons to control and secure a robust gait.

Organization of the Segmental CPG for Locomotion in Rodents

In preparation for a computational model of the neonatal rodent locomotor CPG, it is useful to try to place the identified interneurons into a context where they drive selected components of the motor pattern, including the mechanisms for rhythmogenesis, left-right hind limb coordination, and flexor-extensor alternation within a limb. Although these components have not been studied

in detail using mathematical models, schematics have been developed which could serve as templates for future modeling efforts.

Rhythmogenesis

As described in detail below, studies of the consequences of locomotor deletions during fictive locomotion have implicated the existence of a separate rhythm-generating network within the locomotor CPG, which provides the rhythmic drive for locomotion in the isolated spinal cord. The neuronal composition of the rhythm-generating kernel remains unknown, despite considerable work. Blockade of inhibitory synapses with a combination of GABA and glycine antagonists (Cowley and Schmidt 1995), or targeted deletion of the V1 inhibitory interneurons (Gosgnach et al. 2006), does not eliminate rhythmogenesis, though it can slow the rhythm frequency. A number of results suggest that ipsilaterally projecting glutamatergic neurons are essential for normal rhythmogenesis (Kiehn 2011); rhythmic activity can be generated by an isolated left or right hemicord and even an isolated hemisegment (Kudo and Yamada 1987a; Zhong et al. 2012). Blockade of glutamatergic synapses eliminates the rhythm, and optogenetic excitation of glutamatergic neurons is sufficient to activate locomotor activity (Hagglund et al. 2010). However, the identity of these glutamatergic neurons is not known. Elimination of either of the known glutamatergic interneurons, V2a and V3, affects the locomotor pattern but does not eliminate the rhythm (Crone et al. 2008; Zhang et al. 2008; Crone et al. 2009); neither of these neurons has intrinsic rhythmogenic properties. The Hb9 interneurons show endogenous rhythmicity and are rhythmically active during fictive locomotion; however, their weak and delayed activation during the locomotor cycle (trailing behind the ipsilateral motoneurons they are supposed to drive) suggests that they receive drive from other rhythmogenic neurons (Kwan et al. 2009). The dl6 interneurons contain a subpopulation which is endogenously rhythmic and shows loosely coupled rhythmic firing beginning before the onset of ipsilateral MN activity (Dyck et al. 2012). Dyck et al. propose that these interneurons

may participate in the rhythmic kernel of the locomotor CPG; selective inactivation of these neurons has not yet been accomplished. The rhythmogenic kernel could activate rhythmic firing due to endogenous bursting properties of the kernel interneurons (Brocard et al. 2010), which may only become manifest during activity-dependent changes in extracellular ion concentrations (Brocard et al. 2013). Alternatively, a network of mutually excitatory interneurons with spike frequency adaptation could form the kernel (Kiehn 2011). This network could arise from the combined interactions among several of the currently identified groups (none of which is essential) or an entirely new group that has not yet been specified.

Left-Right Hind Limb Coordination

Through their detailed studies of the commissural interneurons (CINs), Kiehn and colleagues have generated the most sophisticated model for the coordination of left-right limb movements (Fig. 2; Kiehn 2011). Electrophysiological measurements demonstrated the existence of three separate commissural pathways to contralateral motoneurons (Butt and Kiehn 2003). A direct inhibitory pathway uses glycinergic CINs to monosynaptically inhibit contralateral MNs. A disynaptic inhibitory pathway uses glutamatergic CINs to drive contralateral GABAergic and/or glycinergic interneurons which inhibit MNs (Butt and Kiehn 2003; Quinlan and Kiehn 2007). This dual inhibitory commissural pathway could serve to maintain contralateral flexor (or extensor) MNs out of phase with ipsilateral flexor (or extensor) activity. A third pathway uses glutamatergic CINs to directly excite contralateral MNs. These could serve to couple activity of flexors with contralateral extensors; they also appear to coordinate synchronous left-right activity, as seen after blockade of glycinergic synapses with strychnine (Cowley and Schmidt 1995), or in mutants that reduce crossed inhibitory commissural projections (Kullander et al. 2003; Rabe et al. 2009).

In Fig. 2, the direct inhibitory pathway is proposed to be mediated by the V0_D class of inhibitory CINs, while the indirect inhibitory pathway is

Locomotor Pattern Generation in the Rodent Spinal Cord, Fig. 2

Schematic of organization of the commissural system that coordinates left and right limb movements. Excitatory interneurons and synapses are shown in red, while inhibitory interneurons and synapses are shown in blue. Only one half of the network is shown, with identified neurons on the left making synapses onto neurons on the right. See text for details (From Kiehn 2011)

thought to be mediated by the excitatory $V0_v$ and $V3$ commissural interneurons synapsing onto contralateral $V1$ interneurons, including Renshaw cells, Ia inhibitory interneurons, and other unidentified $V1$ neurons (Kiehn 2011). The monosynaptic excitatory pathway is proposed to be mediated by the $V3$ interneurons; in mutant $\text{Netrin-1}^{-/-}$ mice, the $V3$ interneurons are the major surviving commissural pathway, and the motor pattern is synchronous across the cord (Rabe et al. 2009). The $V3$ pathway could also help maintain alternation under normal conditions, as the flexor center on one side could use them to excite the contralateral extensor MNs (Butt and Kiehn 2003). The rhythmic drive to these CINs has not been fully elucidated. However, a subset of the excitatory $V2a$ interneurons form synapses onto members of the $V0_v$ neurons and could help drive the indirect inhibitory commissural pathway (Crone et al. 2008). This is not the only drive to this pathway, as locomotor behavior and fictive locomotion are essentially normal at low frequencies in mutants lacking these neurons; only at higher frequencies is left-right coordination disrupted, suggesting that other unidentified inputs provide the predominant drive to $V0_v$ CINs at lower speeds (Crone et al. 2009). Based on detailed studies of the spinal locomotor CPG in aquatic organisms, CINs are very likely to synapse on neurons in the rhythm-generating kernel of the CPG, as well as other interneurons in the

network. This is indicated in Fig. 2 by the dotted lines to the rhythm center on the right side.

Flexor-Extensor Alternation

The third component of the locomotor pattern is alternation between ipsilateral flexor (F) and extensor (E) motoneurons (Fig. 3; Kiehn 2011). F-E alternation is preserved in isolated hemicord preparations, suggesting that contralateral input, while it may support F-E alternation, is not essential (Kudo and Yamada 1987a; Zhong et al. 2012). Identified ipsilaterally projecting inhibitory interneurons include the heterogeneous $V1$ population and the $V2b$ neurons. In the $V1$ population, the Renshaw cells mainly provide recurrent inhibition to motoneurons (Alvarez et al. 2013). The Ia inhibitory interneurons mediate sensory crossed reflexes that can support F-E alternation: flexor-related Ia-INs inhibit extensor-related Ia-INs and MNs, and vice versa. Both Renshaw cells and IA-INs are rhythmically active during fictive locomotion (Nishimaru et al. 2006). Over 70% of the $V1$ population remains unidentified. Genetic deletion of the entire $V1$ population does not abolish F-E alternation, and some reciprocal inhibition is still detected in the absence of the IA-INs (Gosgnach et al. 2006). The inhibitory GATA 2/3-expressing $V2b$ interneurons could also participate in F-E phasing (Kiehn 2011). Finally, in the intact cord, CINs from the opposite side of the cord could help coordinate ipsilateral flexor-

Schematic organization of the network ensuring flexor-extensor alternation during fictive locomotion. Excitatory interneurons are shown in red, while inhibitory interneurons are shown in blue. Only one side of the spinal cord is shown. See text for details (From Kiehn 2011)

extensor alternation by both excitatory inputs (which could couple contralateral flexors and extensors) and inhibitory inputs (which could simultaneously block contralateral homologs) (Butt and Kiehn 2003). These possible connections are shown in the schematic in Fig. 3.

Computational Models of the Rodent Locomotor CPG

While experimental data have generated many schematics of how the rodent locomotor CPG might be organized, there are few fully realized computational models that allow testing of hypotheses. Sherwood et al. (2011) presented an abstract model of the rodent locomotor CPG, based on interactions between coupled oscillators following the unit burst generator (UBG) approach of Grillner (1981). This model is described in detail in the entry by Sherwood in this volume, so will be only superficially described here. This model explores the consequences of variable levels and patterns of

excitatory and inhibitory connections between intrinsically oscillatory neurons, ranging from a half-center of two neurons with mutual excitation or inhibition to a 12-neuron network with bilateral flexor and extensor oscillators, commissural interneurons, and motoneurons. The neuron models are adapted from a conductance-based model of the respiratory network in the pre-Bötzinger complex (Butera et al. 1999); oscillatory neurons have an appropriate balance of persistent sodium currents (I_{NaP}) and leak currents and show spike frequency adaptation. The full 12-neuron model required significant tuning of synaptic weights and cellular properties to generate stable alternation. A more detailed analysis was made of smaller 2- and 4-neuron networks coupled with variable excitatory and inhibitory synapses. Of the 4-cell models, most rapid convergence to the locomotor pattern was obtained with strong inhibition between ipsilateral flexors and extensors, and different levels of inhibition between flexors (and extensors) on opposing sides of the cord, along with moderately strong excitatory connections between contralateral extensors and flexors;

however, the strength of the synapses had to be very high for significant convergence to the locomotor pattern. This model showed the strong dependence of the locomotor output on the ratios of strengths of synaptic connections between the components of the CPG network.

Rybak and colleagues explored a different set of models of the locomotor CPG, based on experimental studies of spontaneous deletions in locomotor activity during fictive locomotion. First studied in turtles (Stein 2008) and cats (Duysens 1977; Lafreniere-Roula and McCrea 2005; Duysens 2006) and more recently in mice (Zhong et al. 2012), deletions occur when one or more motor roots remain silent when they should fire a rhythmic burst of action potentials; for example, the flexor nerves innervating a limb may fall silent while the extensor nerves fire tonically. In cats, about two-third of these deletions resume activity an integer number of locomotor cycles later and are named “non-resetting” deletions; in neonatal mice, almost all of the deletions are non-resetting. This implies that a “clock” continues to tick during the deletion, when there is sometimes no rhythmic motoneuron output at all. The remaining deletions reset the phase of the next cycle, presumably through resetting the “clock.”

Rybak et al. (Rybak et al. 2006; McCrea and Rybak 2007) formulated a two-layer model of the cat locomotor CPG that could explain the origin of resetting and non-resetting deletions by positing two functional levels in the CPG: a half-center rhythm generator (RG), performing a “clock” function, and determining the rhythmic output of the system, and pattern formation (PF) networks that are driven by rhythmic input from the RG and coordinate the phasing and intensity of the different motoneuron groups to drive locomotion. This model is described in detail by Shevstova in this volume, so is only briefly described here. In this model, the RG is symmetrical, with a half-center organization of mutually inhibitory rhythmogenic flexor and extensor modules: these drive respective interneurons in the flexor and extensor PF networks (which are also mutually inhibitory) which in turn drive their motoneurons to generate the behavior. Resetting deletions,

which do not resume an integer number of cycles later, arise from errors in the RG network, while non-resetting deletions, which do resume an integer number of cycles later, arise from errors in the PF network. Only one limb was modeled, as the cat electrophysiological data were obtained only from one side of the animal.

Zhong et al. (2012) carried out a parallel physiological analysis of spontaneous locomotor deletions during transmitter-evoked fictive locomotion in the isolated neonatal mouse spinal cord. This preparation allowed simultaneous recordings from flexor and extensor ventral roots on both sides of the cord. The general outlines of the cat results were affirmed, but with some significant differences. First, nearly all (over 90%) of deletions were non-resetting, suggesting the stability of the RG network in this preparation. Second, the consequences of flexor and extensor deletions were quite different, suggesting a basic asymmetry in the CPG network organization. During a flexor ventral root deletion, extensor motoneurons fired continuously throughout the period that the flexors were silent. In contrast, during an extensor ventral root deletion, the flexor motoneurons continued to fire rhythmically at the same cycle frequency seen before the deletion. This suggests that the CPG has an asymmetric flexor-dominated architecture, as suggested initially by Pearson and Duysens (1976). Third, virtually all of the non-resetting deletions affected only one side of the cord: flexor and extensor bursts on the opposite side continued with no disturbance. Such uninterrupted contralateral bursting is not required for continuation of the ipsilateral rhythm during non-resetting deletions, however: non-resetting deletions could be observed with an isolated left or right hemicord, and even from a single isolated hemisegment.

The isolated neonatal mouse spinal cord also allowed recordings from identified spinal neurons from the L2 segment during non-resetting flexor deletions (Zhong et al. 2012). Ipsilateral motoneurons lost their rhythmic excitatory synaptic drive and fell silent during a flexor deletion; it appeared that neurons upstream of the motoneurons were falling silent during the deletion. Commissural interneurons, in contrast, continued to receive

rhythmic synaptic drive and fired rhythmically during an ipsilateral motor deletion. The ipsilaterally projecting V2a interneurons fell into two distinct classes during ipsilateral flexor deletions. Type I V2a interneurons continued to receive rhythmic excitatory synaptic drive and fired rhythmically during the deletions. In contrast, the type II V2a interneurons acted like motoneurons: these V2a interneurons lost their synaptic drive and fell silent during the ipsilateral flexor deletion. The strength of synaptic drive to this class was significantly correlated with the strength of the motoneuron bursts. Zhong et al. (2012) hypothesize that the type I V2a INs synapse onto CINs (Fig. 2) and drive CIN activity, especially at higher frequencies; these neurons appear to continue to receive RG-related synaptic drive during non-resetting deletions and may thus be included in the RG network. The type II V2a INs appear to be outside the RG network as they lose rhythmic synaptic drive during non-resetting deletions; these may be output neurons that synapse on and help to drive motoneuron activity.

Rybak and colleagues revised their earlier model to incorporate these new data to generate a model of the rodent CPG (Zhong et al. 2012). In this model, the neurons are modeled by Hodgkin-Huxley-style differential equations for the soma and the dendrite compartments, with different distributions of active currents and their parameters in each compartment, following the methods of Booth et al. (1997). Synaptic interactions are modeled by a time-dependent conductance and the driving force. Each type of neuron is represented by a population of neurons (between 50 and 200 for each type), with variable initial parameters and synaptic strengths.

Initially, Rybak and colleagues modeled the CPG on only one side of the cord (Fig. 4). As with the cat model, this model has two layers, a rhythmogenic RG layer and an organizing PF layer. However, the organization of the RG layer is asymmetrical, to explain the asymmetric consequences of flexor versus extensor deletions in the mouse spinal cord. In the RG layer, only the flexor group (RG-F) neurons show intrinsic rhythmic activity, produced by an I_{NaP} -dependent mechanism with mutual synaptic excitation among

members of the group. The extensor group (RG-E) does not have sufficiently large I_{NaP} to be endogenously rhythmic and fires tonically. These groups drive major populations in the PF network (PF-F and PF-E) which drive locomotor activity in flexor and extensor motoneuron populations, respectively. These reciprocally inhibit one another through inhibitory interneurons. The PF-F group receives rhythmic drive from the rhythmogenic RG-F pacemakers, while the PF-E group is tonically excited by the RG-E group and fires rhythmically due to rhythmic inhibition from the PF-F group. This model can produce robust locomotor-like activity at each level of the network.

The model was then extended to include both sides of the spinal cord, with left and right RG networks connected by inhibitory commissural interneuron pathways between the flexor RG half-centers, excitatory commissural pathways between flexor centers, and contralateral extensor centers, as well as weaker flexor-flexor and extensor-extensor pathways that could maintain synchrony in the absence of inhibition (Fig. 5). Exploration of this model showed that it could reproduce the experimental deletion results (Zhong et al. 2012). For example, hemisection of the cord (modeled by elimination of commissural pathways) slows the cycle frequency by half while maintaining flexor-extensor phasing; analysis showed that the slowing arose primarily from loss of excitatory drive from the contralateral RG-E populations to the rhythmogenic ipsilateral RG-F populations. The model could reproduce the asymmetrical effects of deletions described above. For example, non-resetting flexor deletions resulted in ipsilateral tonic extensor activity but unchanged contralateral activity; this could be obtained by simulated suppression of excitatory input from the ipsilateral RG-F population to the ipsilateral PF-F population; this relieved the PF-E population from rhythmic inhibition to allow it to tonically drive the extensor motoneurons. Simulated loss of tonic input from the nonrhythmic RG-E population silenced the PF-E and extensor motoneuron populations with no effect on rhythmic drive from the RG-F population to the PF-F and flexor motoneurons. These deletion results

formation layer is shown in *blue*. Arrows show excitatory synapses, while *circles* show inhibitory synapses. See text for details (Modified from Zhong et al. 2012)

could also be obtained by loss of synaptic drive at other points in the network. Resetting deletions, which are rare in mice, could be simulated by perturbations at the RG level, for example, temporary inhibition of the rhythmic RG-F population; this is predicted to affect the contralateral population as well.

Preliminary attempts have been made to place the identified interneuron classes within the formal organization of the asymmetric locomotor CPG model. Type I V2a interneurons, which continue to oscillate during non-resetting deletions, are modeled to act within the RG network, though since they do not have rhythmogenic properties they are probably driven by other neuronal

populations. Type II V2a interneurons, which lose synaptic drive and fall silent during non-resetting deletions, are modeled to be among the output paths from the PF network to motoneurons, though they are not the only population of neurons to do so. As described above, many of the other defined interneuron classes are heterogeneous and will require additional molecular analysis to subdivide them into single classes. However, among the neurons that could act within the RG network are the endogenously rhythmic subset of dI6 interneurons and a subset of Hb9 interneurons. Among outputs to motoneurons are another subset of Hb9 interneurons. V1 and V2b interneurons form the Renshaw cells and Ia inhibitory INs in the output

shown in blue, and the commissural network is in pink. Arrows show excitatory synapses, while circles show inhibitory synapses. See text for details (Modified from Zhong et al. 2012)

layer from the PF network; they could also form the inhibitory interneurons that are modeled in the PF and RG networks. Finally the commissural pathways are composed of inhibitory V0 and excitatory V3 interneurons. The model provides predictions of the patterns of synaptic drive that interneurons at different points in the network will receive, both under normal conditions and during deletions of various kinds. Much further work will need to be done to measure these synaptic interactions and verify or correct these predictions.

Future work on models of the rodent spinal locomotor CPG will be able to generate hypotheses for the roles of the various subsets of the cardinal identified interneuron classes and of their synaptic interactions. At present, our knowledge of the interneurons, and the existence and properties of synapses between them, is fragmentary but is the focus of much concerted experimental effort. The interaction of modeling with

experimental work should rapidly push forward our understanding of the rodent locomotor CPG, which can serve as a model for other, more complex neural networks in the nervous system.

Synonyms

[Cerebellar long term depression](#); [Cerebellar LTD](#); [Long term synaptic depression at the parallel fiber-Purkinje cell synapse](#)

Definition

Long-term depression (LTD) in the granule cell-Purkinje cell synapse is a reduction of synaptic transmission efficacy, which lasts for hours or longer. The synaptic transmission at this synapse is mediated via α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA), a member of the ionotropic glutamate receptors, and the direct cause of LTD is a reduction in the numbers of postsynaptic AMPARs. The traditional stimulation to trigger LTD is simultaneous and repeated activation of two excitatory inputs onto Purkinje cells, parallel fibers (PFs) and climbing fibers (CFs), which are neuronal projections originated from granule cells and neurons in inferior olivary nucleus, respectively.

Long Term Depression in the Granule Cell-Purkinje Cell Synapse, Fig. 1 A schematic illustration of two excitatory inputs onto Purkinje cells, CF and PF. Traditional stimulation to induce LTD is simultaneous and repeated stimulation of CF and PF through glass electrodes

Detailed Description

The LTD at synapses between PFs, axons of granule cells, and Purkinje cells (Fig. 1) was first discovered in the 1980s, and the observations of LTD have led to the Marr-Albus-Ito theory (Marr 1969; Albus 1971; Ito 1986), in which some forms of cerebellum-dependent motor learning depend on long-term changes in synaptic transmission at these synapses. Long-term changes, reduction (LTD) or potentiation (LTP), in synaptic transmission efficacy, which is so-called long-term synaptic plasticity, have been observed in a variety of synapses in the brain. Indeed, the synapses between PFs and Purkinje cells could undergo not only LTD but also LTP (Lev-Ram et al. 2002). Such individual forms of long-term synaptic plasticity in several brain areas have their own molecular mechanisms or characteristic features, even though the final outcomes are either reduction or potentiation in synaptic transmission efficacy. Roles of long-term synaptic plasticity are further complicated, although they are mainly thought to be related to learning and memory. Therefore, it is important to know details of individual forms of long-term synaptic plasticity.

There are several ways to describe details of LTD in the granule cell-Purkinje cell synapse, such as history of LTD, mathematical description of LTD, or argument regarding the behavioral

functions of LTD. In this description, LTD will be explained mainly from a standpoint of signaling mechanisms and molecules related to the LTD (Fig. 2).

Stimuli to Trigger LTD

Based on a theory of Albus and Marr (Marr 1969; Albus 1971), who postulated that CFs, another excitatory input onto Purkinje cells (Fig. 1), provide a teaching signal that induces long-term changes in the efficacy of PF-Purkinje cell synapses, stimulation to induce synaptic plasticity at these synapses was explored. Then it was discovered that LTD can be induced when simultaneous and repeated stimulations of PFs and a CF were applied in vivo or in cerebellar slice preparations. In most cases, these stimulations are applied electrically via glass electrodes (Fig. 1). Optimal conditions of such stimulation were also explored. Karachot et al. tested several conditions of stimulation in slice preparations, and they found that simultaneous stimulation of PF and CF at 1 Hz with 300 pulses most effectively induced LTD in terms of amounts and probability of depression (Karachot et al. 1994). Interestingly, similar stimulation with more pulses (500 pulses) is much less effective than 300 pulses. Further, timing between PF and CF stimulation seems to be critical, although precise interval is varied depending on other parameters of stimulation. Specifically, three studies have shown that LTD was effectively induced when PF stimulation preceded CF stimulation with approximately 100 ms, but LTD is not observed by opposite order of stimulation (Chen and Thompson 1995; Wang et al. 2000a; Safo and Regehr 2008). It should be noted that PF stimulation paired with CF stimulation to induce LTD is composed of one pulse in some cases but of a few pulses in other cases. Considering the existence of optimal conditions, the temporally and quantitatively precise regulation of signaling mechanisms seems to be important for triggering LTD.

The LTD described here is a long-term reduction of synaptic transmission at PF-Purkinje cell synapses, so that synaptic transmission has to be measured for the LTD study. At synapses between

Long Term Depression in the Granule Cell-Purkinje Cell Synapse, Fig. 2 A schematic illustration of time course of LTD and signaling mechanisms of LTD induction, expression, and maintenance. See text for abbreviations

PF and Purkinje cells, AMPARs mediate synaptic transmission. Since AMPARs are nonselective cation channels, excitatory postsynaptic potential or current (EPSP or EPSC) can be recorded when AMPARs are activated by glutamate released from PFs. Usually, EPSP or EPSC is recorded by electrophysiological methods, such as extracellular recordings or patch clamp recordings.

Even though paired stimulation of PFs and CFs has been the traditional stimulation that triggers LTD, as understanding of signaling mechanisms of LTD progressed, other stimulations, which can bypass several pathways or directly activate signaling molecules, have been used to induce LTD. For example, depolarizing pulses of Purkinje cells through patch clamp pipette can be used instead of

CF stimulation (Fig. 3; Crépel and Jaillard 1991; Konnerth et al. 1992), because CF stimulation actually results in the depolarization of Purkinje cells that is necessary for LTD. In addition to in vivo or in slice preparations, LTD was observed in cultured Purkinje cells, where there are no longer intact synaptic connections. In order to trigger LTD in cultured Purkinje cells, glutamate receptor agonists were applied while depolarizing Purkinje cells, probably on the idea that the agonists could mimic PF stimulation (Linden et al. 1991). Glutamate has been also utilized to apply LTD stimulation onto whole cerebellar slices, when more tissue samples are required for analyses, such as biochemical, histological, or molecular biological analyses. In these experiments,

Long Term Depression in the Granule Cell-Purkinje Cell Synapse, Fig. 3 An image of cerebellar slice showing the position of patch clamp electrode onto a Purkinje cell and the PF stimulation electrode (*top*), and time course of cerebellar LTD triggered by PF stimulation paired with Purkinje cell depolarization at 1 Hz for 5 min (*bottom*)

slices are treated with glutamate in high-potassium solutions, and such treatment, which can be called chemical LTD stimulation, indeed triggers LTD (Tanaka and Augustine 2008). Moreover, direct increase or activation of signaling molecules, such as increase in intracellular calcium (Ca^{2+}) concentrations or activation of protein kinase C (PKC), could induce LTD (Linden and Connor 1991; Lev-Ram et al. 1997a; Kondo et al. 2005; Tanaka et al. 2007). These alternative stimulations are convenient for certain experimental conditions, effective to show the importance of a specific signaling molecule, or useful to determine the interactions of molecules working for LTD. However, results obtained in different conditions or by different stimulations are sometimes inconsistent. In order to reconcile discrepancy and to fully understand LTD, we may need to consider whether the observations in

certain conditions can be generalized in more physiological conditions.

Time Course of LTD

Long-term synaptic plasticity, including cerebellar LTD, is generally composed of three temporal phases: induction, expression, and maintenance. The synaptic stimulation that triggers LTD usually lasts for a few to several minutes. During this period, the stimulation elevates or activates many signaling molecules, and this period of triggering LTD can be defined as the induction phase. The signaling molecules, which are elevated or activated during the stimulation, sequentially activate downstream molecules and finally cause the reduction of AMPAR numbers at synapses. This period when depression is in process is defined as the expression phase. The time course of expression varies according to stimulus conditions or preparations. In some cases, expression is rapid, so that depression reaches maximum level in a few minutes after the end of stimulation. In other cases, slow and gradual expression, which lasts for 20–60 min, can be observed. Mechanisms that determine the time course of LTD expression are not yet understood. Once depression reaches a maximum level, the depressed level is maintained for a few hours or even longer. The maintenance phase is often divided into early and late phases, latter of which is thought to depend on newly protein synthesis. It is not known whether the depression is terminated and synaptic transmission is returned to the original level after a certain period.

Fast Signals Required for the Induction of LTD

The well-studied and important signals required for the induction of cerebellar LTD are increases in postsynaptic Ca^{2+} concentrations ($[\text{Ca}^{2+}]_i$). The importance of $[\text{Ca}^{2+}]_i$ increase is first demonstrated in the experiments, where Ca^{2+} chelators, EGTA or BAPTA, were introduced into postsynaptic Purkinje cells (Sakurai 1990; Shibuki and

Okada 1992; Konnerth et al. 1992). Such introduction of Ca^{2+} chelators blocks LTD. As mentioned above, the traditional stimulation that triggers LTD at least in cerebellar slice preparations can be the simultaneous and repeated stimulation of CFs and PFs. The stimulation of CFs or PFs causes increases in $[\text{Ca}^{2+}]_i$ in Purkinje cells (Konnerth et al. 1992; Eilers et al. 1997; Wang et al. 2000a). One Purkinje cell receives synaptic inputs from only one CF, but a pair of CF and Purkinje cell makes a few hundreds of synaptic connections. Thus, stimulation of CF activates many AMPARs at the CF and Purkinje cell synapses, so that the CF stimulation strongly depolarizes the innervated Purkinje cell, which in turn activates voltage-dependent Ca^{2+} channels (VDCCs) and induces Ca^{2+} entry through these channels (Ross and Werman 1987; Miyakawa et al. 1992; Konnerth et al. 1992). In contrast, one PF makes only one synapse onto one Purkinje cell, while about 150,000 PFs innervate a single Purkinje cell. At synapses between PFs and Purkinje cells, metabotropic glutamate receptor 1 (mGluR1) exists (Nusser et al. 1994; Baude et al. 1993; Petralia et al. 1998; López-Bendito et al. 2001) and is required for triggering LTD (Aiba et al. 1994; Conquet et al. 1994; Ichise et al. 2000). The mGluR1 is a type of receptor that is coupled with Gq-proteins, whose activation produces inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG) via phospholipase C (PLC). The IP3 produced by PF activity binds and activates IP3 receptors on the endoplasmic reticulum, which is an intracellular Ca^{2+} store, so that $[\text{Ca}^{2+}]_i$ is increased by Ca^{2+} release through IP3 receptors. Such Ca^{2+} release from IP3 receptors is required for LTD (Khodakhah and Armstrong 1997; Inoue et al. 1998; Finch and Augustine 1998; Miyata et al. 2001). Although these pathways of $[\text{Ca}^{2+}]_i$ increase by PF and CF stimulation are superficially distinct, they also cooperate to induce larger $[\text{Ca}^{2+}]_i$ increase. Because paired stimulation of CFs and PFs, but not the stimulation of only CFs or PFs, induces LTD, it has been studied how the coincidence activation of two synaptic inputs is detected. One of the coincidence detection mechanisms is synergistic activation of IP3 receptors by IP3 and

Ca^{2+} (Wang et al. 2000a; Doi et al. 2005; Sarkisov and Wang 2008), which are produced by PF stimulation and are entered through VDCCs after CF stimulation, respectively. Thus, it seems that $[\text{Ca}^{2+}]_i$ increase can reach to the level that is enough for LTD induction, when stimulations of PFs and CFs are paired.

The question was how large $[\text{Ca}^{2+}]_i$ increase is required for LTD. Because $[\text{Ca}^{2+}]_i$ increase triggered by synaptic stimulation is temporally complex and other signaling pathways activated by such stimulation may affect LTD, it is difficult to define the precise $[\text{Ca}^{2+}]_i$ increase required for LTD. Nevertheless, several efforts have been made to know the $[\text{Ca}^{2+}]_i$ increase by PF or CF stimulation. $[\text{Ca}^{2+}]_i$ increase evoked by CF stimulation is reaching around several hundred nanomolar in a wide area of dendrites (Wang et al. 2000a; Schmidt et al. 2003; Sarkisov and Wang 2008). Although $[\text{Ca}^{2+}]_i$ increase evoked by PF stimulation vary depending on the number and frequency of stimulation, $[\text{Ca}^{2+}]_i$ increase produced by a single or a few pulses of PF stimulation, which is often used to induce LTD, could also reach several hundred nanomolar in a part of dendrites where stimulated PF innervates (Finch and Augustine 1998; Wang et al. 2000a). In contrast, paired stimulation of CF and PF produces supralinear $[\text{Ca}^{2+}]_i$ increase, reaching a few micromolar to 10 μM (Wang et al. 2000a; Brenowitz and Regehr 2005), which is higher than the sum of $[\text{Ca}^{2+}]_i$ increase produced by PF and CF stimulation alone. Even though the $[\text{Ca}^{2+}]_i$ increase evoked by single paired stimulation is transient, presumably a few hundred milliseconds, repetitive stimulation could also produces gradually elevated $[\text{Ca}^{2+}]_i$ plateau (Eilers et al. 1995, 1996; Takechi et al. 1998; Finch and Augustine 1998; Wang et al. 2000a), so that repetitive and transient $[\text{Ca}^{2+}]_i$ increase is superimposed on such $[\text{Ca}^{2+}]_i$ plateau.

In order to define precise $[\text{Ca}^{2+}]_i$ required for triggering LTD, relationships between $[\text{Ca}^{2+}]_i$ increase and LTD were determined by using caged Ca^{2+} , which can release Ca^{2+} when photolysis is applied (Tanaka et al. 2007). The monotonic increase in $[\text{Ca}^{2+}]_i$ was produced by the photolysis of caged Ca^{2+} introduced into

Purkinje cells, and the resultant LTD was measured. The relationships can be described by Hill equation with Hill coefficient of around 5, so that there is a threshold of $[Ca^{2+}]_i$ for triggering LTD. Further, in this series of experiments, several durations of $[Ca^{2+}]_i$ increase were tested. It was found that the $[Ca^{2+}]_i$ threshold of peak amplitude is higher when shorter duration of $[Ca^{2+}]_i$ increase is applied. In case that 0.5, 1, 15, or 30 s duration of photolysis was applied, $[Ca^{2+}]_i$ threshold is 2.8, 1.8, 1.1, or 0.9 μ M, respectively. This suggests that peak $[Ca^{2+}]_i$ is not an absolute determinant for LTD. In contrast, more integrated $[Ca^{2+}]_i$ is necessary when longer duration of $[Ca^{2+}]_i$ increase is applied. The relationship between the threshold level of integrated $[Ca^{2+}]_i$ for LTD and duration of $[Ca^{2+}]_i$ increase fits to the leaky integrator property, similar to the “leaky integrate and fire” concept used in models of neuronal electrical signaling (Knight 1972; Fohlmeister et al. 1977). The leaky integrator for Ca^{2+} -triggered LTD can be expressed by an equation:

$$\tau \frac{dx}{dt} = -x + a[Ca^{2+}]_i(t)$$

where τ is the time constant of the integration, x is the amount of a hypothetical downstream signal that transduces Ca^{2+} into LTD, and a is a scaling factor representing the efficacy of the integrator in converting Ca^{2+} into x . This suggests that, while $[Ca^{2+}]_i$ increase activates molecules that positively work for LTD, negative regulators seem to gradually become active during longer duration of $[Ca^{2+}]_i$ increase. The leaky integrator property of LTD triggering may be the reason why 500 pulses of paired stimulation of PF and CF are less effective than 300 pulses (Karachot et al. 1994). Thus, the analysis using caged Ca^{2+} defined $[Ca^{2+}]_i$ required for LTD, which depends on the duration of $[Ca^{2+}]_i$ increase.

In addition to Ca^{2+} -related signals described above, the stimulation of PF and CF could elevate or activate other signals that are superficially independent to these Ca^{2+} signals. PF stimulation can trigger the release of nitric oxide (NO) from PF terminals or stellate cells (Shibuki and Okada

1991; Lev-Ram et al. 1997b; Namiki et al. 2005), the latter of which are interneurons in the molecular layer. Several studies demonstrated that NO is involved in LTD (Ito and Karachot 1990; Cr  pel and Jaillard 1990; Shibuki and Okada 1991; Daniel et al. 1993; Lev-Ram et al. 1995; Reynolds and Hartell 2001). Although NO cannot induce LTD by itself, NO cooperates with sub-threshold level of Ca^{2+} , which is not sufficient to induce LTD (Lev-Ram et al. 1995, 1997a), so that NO is considered to play a permissive role for LTD. Considering that NO is generally known to activate guanylate cyclase (GC) (Jaffrey and Snyder 1995; Calabrese et al. 2007), the roles of NO for LTD are thought to be as follows. NO released from PF or stellate cells diffuses into Purkinje cells and activates GC, which produces cyclic guanosine monophosphate (cGMP). The cGMP activates cGMP-dependent protein kinase (PKG), which reduces protein phosphatase 2A (PP2A) activities. Phosphorylation of molecules, such as AMPARs, is necessary for LTD, so that the reduction of PP2A activities positively works for LTD. In fact, inhibition of GC or PKG blocked LTD, and inhibition of PP2A itself could induce synaptic depression (Ito and Karachot 1990; Hartell 1994; Reynolds and Hartell 2001; Endo et al. 2003; Launey et al. 2004). These results suggest that this NO-mediated pathway is likely one mechanism working for LTD induction. Further, because it is reported in other types of cells that cGMP facilitates Ca^{2+} release from IP3 receptors via PKG activation (Guihard et al. 1996; Rooney et al. 1996; Wagner et al. 2003) and the IP3-dependent Ca^{2+} release is critical for cerebellar LTD (Khodakhah and Armstrong 1997; Inoue et al. 1998; Finch and Augustine 1998; Miyata et al. 2001), a pathway of NO, cGMP, and PKG may also contribute to induce higher $[Ca^{2+}]_i$ increase. Thus, NO may have dual roles for LTD induction.

Another molecule released upon the PF stimulation is endocannabinoid, which is known as a retrograde messenger. In the cerebellar cortex, 2-arachidonoyl glycerol (2-AG) is released from Purkinje cells (Maejima et al. 2005). Because local $[Ca^{2+}]_i$ increase due to AMPAR-mediated depolarization and mGluR1

activation cooperatively produce endocannabinoid (Maejima et al. 2001; Brown et al. 2003; Marcaggi and Attwell 2005), relatively strong PF stimulation, such as a brief burst of PF stimulation, seems to trigger the release of 2-AG. 2-AG is produced by diacylglycerol lipase from DAG (Sugiura et al. 2006), which is produced by PLC after the activation of mGluR1 and Gq-protein. Because the PLC, specifically PLC β 4, is also sensitive to Ca²⁺, strong PF stimulation activates PLC β 4 via Gq-protein and Ca²⁺ and in turn leads to 2-AG release via DAG production (Maejima et al. 2005). The function of endocannabinoid as a retrograde messenger has been well studied to explain the mechanism of short-term synaptic depression at PF and Purkinje cell synapses (Maejima et al. 2001; Brown et al. 2003; Marcaggi and Attwell 2005), which depends on the reduction of glutamate release via presynaptic cannabinoid receptor type 1 (CB1R) (Yoshida et al. 2002). Endocannabinoid signaling is also involved in cerebellar LTD, because LTD was impaired in the presence of a CB1R antagonist or a diacylglycerol lipase inhibitor or in CB1R knockout mice (Safo and Regehr 2005). Further, LTD was not observed even in mice lacking CB1Rs selectively in cerebellar granule cells (Carey et al. 2011). It is known that LTD is postsynaptically induced, so that it remains elucidated how retrograde endocannabinoid signaling and presynaptic CB1Rs affect postsynaptically induced LTD.

Corticotropin-releasing factor (CRF) exists in the CF (Palkovits et al. 1987; Sakanaka et al. 1987; Cummings et al. 1994), so that CRF can be released from CF terminals. On the other hand, mRNA of CRF receptors is detected in Purkinje cells (Chang et al. 1993; Potter et al. 1994). A study demonstrated that antagonists of CRF receptors blocked not only LTD induced by conjunctive stimulation of PF and CF but also LTD induced by the pairing of PF stimulation with Purkinje cell depolarization (Miyata et al. 1999). Further, LTD was not observed in animals, whose CF was chronically destructed, but it was restored by CRF replenishment (Miyata et al. 1999). According to these results, it is

thought that spontaneously released CRF from CF, rather than CRF released by CF stimulation during LTD induction, plays a permissive role in LTD.

As described above, DAG is produced via mGluR activation. Although there has been no direct evidence showing that DAG produced by mGluR activation is truly required for LTD, DAG may cooperate with Ca²⁺ to activate downstream molecules, such as PKC, or may contribute to produce 2-AG.

Mechanisms Required for Expression of LTD

The expression of LTD correlates with a reduction in the number of synaptic AMPARs, and the reduction is due to the enhancement of AMPAR internalization by clathrin-mediated endocytosis (Wang and Linden 2000). The enhancement of AMPAR internalization is triggered by PKC-dependent phosphorylation of GluR2, an AMPAR subunit, at serine 880 (Ser880) (Matsuda et al. 2000; Xia et al. 2000; Chung et al. 2003). While dephosphorylated GluR2 interacts with glutamate receptor-interacting protein/AMPA receptor-binding protein (GRIP/ABP), which is the postsynaptic density-95/discs-large/zonula occludens-1 (PDZ) domain-containing protein, via PDZ-binding motif of GluR2, such interaction is prevented by the PKC-dependent phosphorylation of GluR2 (Matsuda et al. 2000; Xia et al. 2000). The unbinding of GRIP/ABP itself or the following interaction of phosphorylated GluR2 with another PDZ domain-containing protein, PICK1, leads to the endocytosis of AMPARs (Steinberg et al. 2006).

Among several subtypes of PKC, PKC α has been shown to be responsible for the LTD, because knockdown of PKC α blocked LTD (Leitges et al. 2004). Given that PKC α is a Ca²⁺-dependent form of PKC, it is likely that PKC α is activated by Ca²⁺. However, even though such a Ca²⁺-dependent PKC α activation might be sufficient for the AMPAR internalization during rapid expression of LTD, it cannot explain the gradual expression of LTD, which is often observed,

because $[Ca^{2+}]_i$ increase is transient (Konnerth et al. 1992; Eilers et al. 1997; Tanaka et al. 2007). To fill the temporal gap, a positive feedback kinase loop is shown to be responsible for the prolonged PKC activation and consequently gradual expression of LTD (Kuroda et al. 2001; Tanaka and Augustine 2008). This loop includes several molecules. PKC phosphorylated Raf-kinase inhibitory protein (RKIP). RKIP usually binds and inhibits Raf1 and MEK, which are upstream kinases of mitogen-activated protein kinase/extracellular-signal-regulated kinase (MAPK/Erk), but phosphorylated RKIP dissociates from these molecules, so that the Raf1-MEK-MAPK pathway can be activated (Yamamoto et al. 2012). MAPK directly phosphorylates and activates phospholipase A2 (PLA2), and PLA2 produces arachidonic acid, which can activate PKC directly or indirectly via cyclooxygenase-2 and prostaglandin D₂ or E₂ (Le et al. 2010). Thus this loop can extend the timing of PKC activation, so that LTD is gradually expressed.

As described above, it is well known that PKC-dependent phosphorylation of GluR2 AMPARs is important for LTD. However, it is not known whether other molecules in the positive feedback loop have roles in LTD, except for working as components of this loop. Specifically, since MAPK generally has many target molecules and is involved in several cellular events, it is interesting to elucidate another function of MAPK in LTD.

Involvement of this positive feedback loop fits well to the time course of gradual expression of LTD. Although it is not clear whether this loop is also required for LTD with rapid expression, this loop and similar regenerative system may be generally attractive mechanisms for long-term synaptic plasticity. One of the important aspects of long-term synaptic plasticity is that such plasticity is generally triggered by transient synaptic stimulation but lasts for a long time, so that some mechanisms seem to work for the temporal conversion from transient stimulation to long-term signaling activities. The positive feedback loop working for the cerebellar LTD is likely one example of such mechanisms.

Mechanisms Required for Maintenance of LTD

Compared with the induction and expression, considerably less is known about mechanisms required for LTD maintenance. Nevertheless, studies using cultured Purkinje cells demonstrated the requirements for transcriptional and translational cellular events in the late phase of LTD, which is defined as a phase beginning 60 min after induction. Activity-driven transcriptional regulators, the cyclic AMP (cAMP)-responsive element-binding protein (CREB) and the Ca^{2+} -/calmodulin-dependent protein kinase type IV (CaMKIV), were implicated in this phase (Ahn et al. 1999), although it is not clear which transcripts are regulated by these transcriptional regulators. Another transcriptional regulator, serum response factor (SRF), was also implicated in the late phase of LTD. In case of SRF, a target transcript is also shown. SRF binds to the SRE 6.9 site in the promoter region of the synaptic protein Arc, so that Arc is expressed in an SRF-dependent manner (Smith-Hicks et al. 2010). Further, the late phase of LTD is reported to require persistent dynamin-mediated endocytosis, which may also depend on Arc expression (Linden 2012).

These studies using cultured Purkinje cells have advanced our understanding of the maintenance mechanisms of LTD. However, there are still some questions to be addressed. The first question is whether the abovementioned signaling molecules are also involved in late-phase LTD in slice preparations or in vivo. In fact, it is not clear whether or when newly synthesized protein-dependent late-phase LTD is initiated in slice preparations, because bath application of translational inhibitors already blocks its induction (Karachot et al. 2001). Even if we assume that similar mechanisms observed in cultured Purkinje neurons account for the maintenance of the late phase of LTD in intact cerebellar networks, it still has to be elucidated how early maintenance between the expression phase and late phase is achieved. A conceptual model and an analysis of experimental results suggest that another type of bistable switch, which shows threshold behavior, works after the positive feedback loop described

above (Kawato et al. 2011; Kim and Tanaka-Yamamoto 2013).

Spatial Aspects of LTD

Spatial aspects of long-term synaptic plasticity can be represented by homosynaptic and heterosynaptic plasticity. Long-term synaptic plasticity is typically input-specific, meaning that long-term changes in synaptic transmission occur only in synapses, where synaptic plasticity-inducing activities are applied. This is called homosynaptic plasticity. In contrast, when synaptic plasticity is triggered at synapses, where activities are not applied, this is called heterosynaptic plasticity. While cerebellar LTD appears to be homosynaptic when LTD is induced by pairing weak PF activity with CF activity (Wang et al. 2000a), it has also been shown that cerebellar LTD induced by pairing stronger PF activity with CF activity can spread to nearby inactive PF synapses (Wang et al. 2000b; Reynolds and Hartell 2000). Mechanisms of this heterosynaptic LTD are not understood. One suggestion arose from experiments of LTD induced by uncaged Ca^{2+} . The uncaged Ca^{2+} -induced LTD does not spread beyond the area of $[\text{Ca}^{2+}]_i$ increase (Tanaka et al. 2007), so that downstream signals of Ca^{2+} are unlikely key factors for spreading LTD, although they may cooperate with other molecules, such as IP3 or lower concentration of $[\text{Ca}^{2+}]_i$. Since NO is a gas messenger, NO was thought to be a candidate of spreading molecules (Reynolds and Hartell 2001), yet it was demonstrated that NO released by PF stimulation did not spread as expected (Namiki et al. 2005).

Other Signaling Mechanisms Involved in LTD

Although many molecules are already discussed in this description, there are still several other molecules that have been shown to be involved in LTD. Some of them are introduced below.

A member of ionotropic glutamate receptor, $\delta 2$ glutamate receptor (GluD2 or GluR $\delta 2$), is

predominantly expressed on the postsynaptic sites of synapses between PFs and Purkinje cells (Landsend et al. 1997; Zhao et al. 1998). In GluD2-null mice, the numbers of PF-Purkinje cell synapses are severely reduced (Kurihara et al. 1997; Lalouette et al. 2001) and LTD is impaired (Kashiwabuchi et al. 1995; Motohashi et al. 2007), so that GluD2 has two functions on PF-Purkinje cell synapses. These two functions are distinct, because expression of mutant GluD2, which lacks a PDZ ligand domain at C-terminus, rescued the morphological abnormality, but not the impairment of LTD (Uemura et al. 2007; Kakegawa et al. 2008). Unlike other ionotropic glutamate receptors, such as AMPARs, GluD2 does not normally function as an ion channel for LTD (Kakegawa et al. 2007), even though GluD2 is included as a member of ionotropic glutamate receptor. Instead, the C-terminal PDZ ligand domain of GluD2 has functions to regulate intracellular signaling. It is indeed demonstrated that GluD2 interacts with the tyrosine phosphatase PTPMEG via the PDZ ligand domain and regulates phosphorylation of GluR2 AMPARs at tyrosine 876 (Tyr876) (Kohda et al. 2013). The dephosphorylation of Tyr876 of GluR2 via GluD2 and PTPMEG allows GluR2 to be phosphorylated at Ser880, which is required for LTD. Thus, GluD2 gates the LTD by coordinating interactions between two phosphorylation sites of GluR2.

Another type of ionotropic glutamate receptor, *N*-methyl-D-aspartate receptor (NMDAR), is critical in many forms of synaptic plasticity. However, NMDAR was originally excluded from mechanisms of cerebellar LTD, because it was believed that NMDAR was not expressed in Purkinje cells, based on studies using young animals (Perkel et al. 1990; Llano et al. 1991). On the other hand, when adult animals were used, the expression of NMDAR was detected at postsynaptic sites of CF-Purkinje cell synapses (Piochon et al. 2007; Renzi et al. 2007). Then, it is demonstrated that NMDAR at CF-Purkinje cell synapses contributes to the CF-dependent $[\text{Ca}^{2+}]_i$ increase and LTD in adult animals (Piochon et al. 2010). In addition, NMDAR at presynaptic sites of PF terminals or stellate cells are also shown to be

involved in LTD (Casado et al. 2002; Shin and Linden 2005).

For the hippocampal LTP, calcium-/calmodulin-dependent protein kinase II (CaMKII) has been intensively studied, and it is indeed demonstrated that CaMKII is an important mediator for LTP (Lisman et al. 2012). The involvement of CaMKII in cerebellar LTD was not investigated for a long time, probably because other kinases, specifically PKC, have been already shown to be critical for LTD. Yet it was demonstrated that α CaMKII knockout mice show impairment of LTD or even show LTP upon the stimulation that usually triggers LTD in wild-type mice (Hansel et al. 2006). Further, β CaMKII knockout mice show opposite direction of synaptic plasticity: LTP is triggered by a stimulation that usually triggers LTD in wild-type mice, while LTD is triggered by a stimulation that usually triggers LTP in wild-type mice (van Woerden et al. 2009). Detailed mechanisms of these phenomena were not fully understood. However, a combined study of computational model and experiments using cultured Purkinje cells proposed that CaMKII gates LTD by reducing PP2A activities via several steps (Kawaguchi and Hirano 2013). In their model, CaMKII negatively regulate phosphodiesterase1 (PDE1), which degrades cGMP and consequently reduces PKG activities. Thus, negative regulation of PDE1 by CaMKII leads to PKG activation, which in turn reduces PP2A activities. The pathway of cGMP-dependent PKG activation is triggered by NO, as mentioned above, so that NO seems to be capable of compensating the lack of CaMKII activities.

Kinetic Model of LTD

Mathematical description is not a focus of this description, so that details of computational model are not described here. However, it is probably worth to mention the contribution of computational models of kinetic simulations. As described here, signaling mechanisms of LTD are complex and many molecules are implicated in LTD. To systematically understand the

interaction of molecules and characteristic aspects produced by these signaling mechanisms, a computational model of kinetic simulation has been effective. A kinetic model indeed first incorporated the positive feedback loop of PKC and MAPK as a mechanism to expand the timing of PKC and MAPK activation as well as AMPAR phosphorylation (Kuroda et al. 2001). This model also succeeded to reproduce the permissive role of NO. A slightly modified version of this model was then used to explain the relationship between $[Ca^{2+}]_i$ and LTD (Tanaka et al. 2007). Then the model suggested that the sigmoidal relationship arose at least in part from the positive feedback loop. Although this model reproduces most of features in the relationship, there is one feature that the model predicts differently from experimental results. The slope of sigmoidal curve for the relationship is steeper in the model than that in the experimental results. In other words, the model predicts all-or-none induction of LTD, while intermediate level of LTD is observed in experiments. However, if the distribution and noise of $[Ca^{2+}]_i$ increase are considered, a similar curve could be obtained. In contrast, another computational study considered stochastic features of signaling in LTD by taking into account only a few tens of molecules being involved in the LTD process within a confined region like a dendritic spine (Antunes and De Schutter 2012). This stochastic model actually reproduces experimental relationship between $[Ca^{2+}]_i$ and LTD without including the effects of distribution and noise of $[Ca^{2+}]_i$ increase. Thus, it may be interesting to directly test such stochastic features by experiments.

Postsynaptic LTD and LTP

In addition to LTD, two forms of LTP can be also triggered at the PF-Purkinje cell synapses. One is presynaptic LTP, which is induced by a few minutes of PF stimulation at 4 Hz. This presynaptic LTP is mediated by cAMP and protein kinase A (PKA) and relies on the potentiation of glutamate release (Salin et al. 1996). Because LTD is postsynaptically induced and expressed, it was believed that there should be postsynaptic LTP

as a mechanism of resetting LTD. Indeed, another form of LTP is postsynaptic LTP (Lev-Ram et al. 2002), which seems to depend on GluR2 trafficking (Kakegawa and Yuzaki 2005). The LTP is induced by 5 min of PF stimulation at 1 Hz and requires NO, but not cAMP, PKA, cGMP, or PKG. In clear contrast to LTD, this LTP requires the activation of protein phosphatases (PPs), PP1, PP2A, and PP2B (Belmeguenai and Hansel 2005). As expected, LTD can be canceled, when this LTP protocol is applied after LTD is saturated. Oppositely, when LTD protocol is applied after LTP is saturated, LTP can be canceled (Lev-Ram et al. 2003; Coesmans et al. 2004). Thus the postsynaptic LTD and LTP reset each other.

The postsynaptic LTD can be triggered by 5 min of PF stimulation at 1 Hz with concomitant CF stimulation, while the postsynaptic LTP can be triggered by the same PF stimulation without concomitant CF stimulation. It has been discussed regarding the signaling mechanisms to distinct LTP and LTD. Because CF stimulation is the difference between stimulation causing LTD and LTP, one idea is that Ca^{2+} concentration during stimulation may determine the direction of synaptic plasticity. Relatively higher concentrations of $[\text{Ca}^{2+}]_i$ increase is required and is even sufficient for LTD. In contrast, LTP is blocked by 15–30 mM BAPTA, a Ca^{2+} chelator, but not by 5 mM BAPTA (Coesmans et al. 2004). This indicates that lower concentration of Ca^{2+} seems to be necessary for LTP, although it is not clear whether $[\text{Ca}^{2+}]_i$ increase is required or basal level of $[\text{Ca}^{2+}]_i$ is enough for LTP. Based on these results, “inverse BCM rule” has been proposed (Coesmans et al. 2004). BCM stands for Bienenstock, Cooper, and Munro, who originally proposed the “BCM rule,” which is a theory to describe how the threshold of synaptic plasticity is determined (Bienenstock et al. 1982). Based on the BCM rule, lower and higher $[\text{Ca}^{2+}]_i$ increases are associated with the induction of LTD and LTP, respectively. In case of PF-Purkinje cell synapses, the requirement of $[\text{Ca}^{2+}]_i$ for LTD and LTP is opposite, so that “inverse BCM rule” was proposed. However, because LTD, but not LTP, was observed by $[\text{Ca}^{2+}]_i$ increase upon uncaging Ca^{2+} ,

the amplitude of $[\text{Ca}^{2+}]_i$ may not be a sole factor to determine the direction of synaptic plasticity in PF-Purkinje cell synapses. Probably, the combination of Ca^{2+} signals with other signals, such as NO, balances the activities of protein phosphatases and kinases and consequently triggers either LTD or LTP (Lee 2006).

Roles of LTD

Even though LTD was originally found as a cellular basis of motor learning, the relationship between LTD and motor learning is still controversial. In many studies using genetically modified animals, in which signaling molecules required for LTD are modified, it has been demonstrated that motor learning is impaired in these animals (Yuzaki 2013). These studies support the idea that LTD is important for motor learning. In contrast, there are also reports showing discrepancy between cerebellar LTD and motor learning. For example, in mice that do not show LTD due to the genetic modification causing inhibition of AMPAR internalization in Purkinje cells, several types of motor learning were intact (Schonewille et al. 2011). Thus, the relationship between LTD and motor learning has to be further elucidated. However, if LTD would not play a role in motor learning, the question is what would be the roles of LTD. Given that LTD is induced by the conjunctive stimulation of two excitatory inputs and is precisely regulated by many signaling molecules, it is difficult to imagine that LTD does not have any functions. LTD seems to have at least an impact on the function of cerebellar neural networks, because it was reported that the pause of simple spikes in Purkinje cells, which is seen after burst stimulation of PFs, is modified by the induction of LTD (Steuber et al. 2007).

Long Term Synaptic Depression at the Parallel Fiber-Purkinje Cell Synapse

► [Long Term Depression in the Granule Cell-Purkinje Cell Synapse](#)

Long-Term Plasticity, Biophysical Models

Claudia Clopath

Department of Bioengineering, Imperial College London, London, UK

Definition

Connections between neurons are called synapses. Their strength is defined as the voltage amplitude, or slope, of a postsynaptic neuron response to a presynaptic action potential. The synapses can change in strength, i.e., they are plastic, and these changes can operate on different time scales. Long-term plasticity denotes the synaptic changes that last more than 20–30 min (see Fig. 1). This is opposed to short-term plasticity that lasts hundreds of milliseconds.

Models of synaptic plasticity describe mathematically how synapses change under which factors. They are often formulated as differential equations. Biophysical models describe how biophysical quantities, such as spike timing, voltage, calcium, and Ca^{2+} /calmodulin-dependent protein kinases (CaMKII), influence changes in synaptic strength. These latter models can also be called bottom-up. If the variables of the model are only a few biophysical quantities (e.g., only spike timing) or are abstract quantities, they are called phenomenological models (although there is no sharp distinction). Biophysical models are opposed to optimal or top-down models, designed to optimally fulfill a function (see Fig. 2).

Detailed Description

This entry is first describing the basic mechanism of synaptic plasticity and presenting the different experimental evidence of long-term plasticity, before describing the different models of long-term plasticity, from the most simple ones to the most detailed ones.

Synaptic Plasticity

Two neurons can be connected via chemical and/or electrical (gap junction) synapses. A chemical synapse is placed between the axon of a presynaptic neuron and a dendrite of the postsynaptic neuron forming a unidirectional connection. The classical view of the synaptic communication mechanism is as follows: when a presynaptic spike arrives at the presynaptic terminal, neurotransmitters, typically glutamate for excitatory synapses, are released. They can bind on the postsynaptic side to receptors, such as N-methyl-d-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. AMPA receptors then open and let sodium ions flow into the cell, resulting in a depolarization of the postsynaptic membrane potential. The NMDA receptor opens only if at the same time (a) the glutamate binds to the receptors and (b) the postsynaptic cell is depolarized, freeing the magnesium block (see Fig. 3). This depolarization of the postsynaptic cell typically comes from back-propagating action potentials. The NMDA receptor is therefore seen as a coincidence detector between presynaptic and postsynaptic activities. The opening of these receptors allows calcium to enter the synapse. Despite the detailed description of the mechanisms that allow synaptic communication (Lisman and Zhabotinsky 2001; Rubin et al. 2005), the mechanism that leads to changes in the synaptic strength is not completely clear. Calcium plays an important role for further cascade signaling, which acts on AMPA receptor activation through kinases and phosphatases (Lisman et al. 2002). Moreover retrograde messengers like endocannabinoids can influence plasticity, in particular for depression of the synapses (Nevian and Sakmann 2006; Piomelli 2003; Sjöström et al. 2003, 2004).

Long-Term Plasticity, Biophysical Models,

Fig. 1 Cartoon of long-term plasticity. The synaptic strength is defined as the height, or the slope, of the postsynaptic voltage response (postsynaptic potential [PSP]) to a presynaptic spike. If the weight is increased, it is called potentiation, and if it is decreased, it is called depression. Long-term plasticity denotes the changes that last more than 20 min

Long-Term Plasticity, Biophysical Models,

Fig. 2 Models of synaptic plasticity. Biophysical models denote models that take into account biophysical quantities in order to explain synaptic plasticity. If the biophysical quantities are restricted or abstract, the models are called phenomenological. These models are also called bottom-up, since they are based on biophysical quantities but

ultimately can be used to describe brain functions (bottom for biophysical quantities and up for brain functions). This is opposed to functional or optimal models, designed to optimize a function. These models can then be related to biophysical qualities and are thus also called top-down models (top for function and down for biophysical implementation)

Experimental Evidence of Long-Term Plasticity

The typical measurement of synaptic strength is the amplitude or the slope of the excitatory postsynaptic potential (EPSP), i.e., the potential response to a single (or a group of coincident) presynaptic spike(s). Synaptic plasticity can be separated by two different time scales: short-term plasticity, where changes persist during a

few hundred milliseconds, and long-term plasticity that lasts more than 20 min. Short-term plasticity is believed to be presynaptically expressed (Gupta et al. 2000; Markram et al. 1998) and is partly caused by the limited number of neurotransmitters at the synapse. It is well modeled by a reservoir that partially empties at the presynaptic spike time (with a certain probability) and recovers with a certain time constant (Abbott

Long-Term Plasticity, Biophysical Models,

Fig. 3 Cartoon of a glutamatergic synapse. When a pre-synaptic spike arrives at the synapse, neurotransmitters are released in the synaptic cleft. They can bind to the NMDA receptor, and if at the same time the postsynaptic cell is depolarized, the channel opens. Calcium enters the cell, which induces a molecular cascade that phosphorylates the Ca^{2+} /calmodulin-dependent protein kinases (CaMKII), which in turn acts on the AMPA receptor activation. Neurotransmitters can also directly bind to AMPA receptor, opening the channel, allowing sodium to enter, and leading to a depolarization called excitatory postsynaptic potential (EPSP)

et al. 1997; Markram and Tsodyks 1996). Here the focus is on long-term plasticity, which can be induced by different types of protocols.

- (i) Simultaneous voltage clamp and presynaptic stimulations (Ling et al. 2002; Ngezahayo et al. 2000; Fig. 4a). If the cell is slightly depolarized while receiving presynaptic inputs, the synaptic weight is depressed, whereas if the cell is highly depolarized, the synapse is potentiated.
- (ii) Extracellular presynaptic stimulations at different frequencies (Dudek and Bear 1993; Kelso et al. 1986; O'Connor et al. 2005; Fig. 4b). Low-frequency stimulation leads to depression, whereas high frequency leads to potentiation.
- (iii) Pairing of presynaptic and postsynaptic spikes at different time lags (Fig. 4c). In pyramidal cells pre-post pairing typically results in

potentiation, whereas post-pre results in depression (Bi and Poo 1998; Markram et al. 1997) (although it depends on the system (Bell et al. 1997; Egger et al. 1999; Lu et al. 2007; Tzounopoulos et al. 2004)).

- (iv) Pairing at different frequencies (Markram et al. 1997; Sjöström et al. 2001; Fig. 4d). Pre-post pairing at low frequency does not change the synaptic weight; increasing the frequency leads to potentiation.
- (v) Induction of various spike patterns. Synaptic plasticity can also be induced with different patterns, such as triplets of spikes (Froemke and Dan 2002), bursts (Gustafsson et al. 1987; Nevian and Sakmann 2006), quadruplets (Wang et al. 2005), or natural spike trains (Froemke and Dan 2002). The resulting plasticity depends on the protocol: in particular it depends if presynaptic stimulation is extracellular (many inputs at the same time, slices more active) (Froemke and Dan 2002) or intracellular (Sjöström et al. 2001).
- (vi) Synaptic tagging experiments (Frey and Morris 1997). These experiments provide evidence for another separation of time scales of long-term plasticity. The early phase of long-term plasticity lasts 2–3 h and can be induced by tetanic stimulation for potentiation (Fig. 4e). The late phase, or consolidation phase, lasts more than 10 h (i.e., the time of those experiments) and can be induced by a stronger extracellular tetanus that also stimulates dopaminergic fibers (Fig. 4f). Neuromodulation is therefore critical in the process of consolidation (Pawlak et al. 2010; Reymann and Frey 2007).

Models

This section is describing the different models of long-term plasticity, from the most simple ones to the most detailed ones, starting from firing rate models all the way to detailed biophysical models.

Models Based on Firing Rates

The first models of synaptic plasticity in line with Hebb's principle ("Who fires together wires

Long-Term Plasticity, Biophysical Models,

Fig. 4 Different experimental protocols. (a) Voltage clamp experiment. The postsynaptic voltage is clamped at the soma during extracellular presynaptic stimulation. If the voltage is hyperpolarized, no weight change is recorded; for slight depolarization, depression is observed; for strong depolarization, potentiation occurs (Figure redrawn from Artola et al. (1990)). (b) Presynaptic frequency dependence. Extracellular presynaptic spike trains at different frequencies are induced.

Low-frequency stimulation yields depression, whereas high-frequency stimulation results in potentiation. (Figure redrawn from Dudek and Bear 1993). (c) STDP experiment. Pairs of presynaptic and postsynaptic spikes are elicited, while the lag between the presynaptic spike and the postsynaptic spike varies. Pre-post pairing induces long-term potentiation (LTP), whereas post-pre leads to long-term depression (LTD). (Figure redrawn from Bi and Poo 1998). (d) Pairing frequency experiment. Here the lag between the pre- and

together”) (Hebb 1949) depend on the correlation of the pre- and postsynaptic firing rates. The subsequent models subtracted a baseline so that the weight can also be depressed (covariance rule (Sejnowski and Tesauro 1989)), added weight dependency (hard or soft bounds), and added normalization to induce competition between weights (Miller and MacKay 1994). Multiplicative normalization was introduced in Oja’s rule (Oja 1982), which performs principle component analysis (PCA). At the same time, the Bienenstock-Cooper-Munro (BCM) rule (Bienenstock et al. 1982) was designed with a nonlinearity in the postsynaptic firing rate and a sliding threshold, as a homeostatic mechanism. The BCM model also exhibits properties of selectivity in the inputs.

Models Based on Spike Timing

Spike-timing-dependent plasticity (STDP) models (Gerstner et al. 1996; Gütiğ et al. 2003; Karmarkar and Buonomano 2002; Kempster et al. 1999; Rubin et al. 2001; Senn et al. 2001; Song et al. 2000; van Rossum et al. 2000) depend on the precise timing of the pre- and postsynaptic spike.

Standard Pair-Based Models

For the LTD part, standard pair-based models assume that presynaptic spike arrival, at synapse i , induces depression of the synaptic weight w_i by an amount that is proportional to $\bar{y}$, an exponential low-pass-filtered version of the postsynaptic spike train $Y(t)$ with a time constant τ_- (see Fig. 5b, trace post):

$$\tau_- \frac{d}{dt} \bar{y}(t) = -\bar{y}(t) + Y(t),$$

where $Y(t)$ is expressed as the series of short pulses at time t^n , with n being a spike index, $Y(t) = \sum_n \delta(t - t^n)$. The variable $\bar{y}$ is an abstract

variable which could, for instance, reflect the level of calcium concentration (Lisman 1989), the release of endocannabinoids (Sjöström et al. 2004), or the back-propagating action potential, although such an interpretation is not necessary for this type of phenomenological rules. Similarly, the presynaptic spike train is described as a series of short pulses at time t_i^n with i being the index of the synapse, $X_i(t) = \sum_n \delta(t - t_i^n)$. The depression is then modeled as the following equation (see Fig. 5b):

$$\frac{d}{dt} w_i^- = -A_{\text{LTD}}(w_i^-) X_i(t) \bar{y}(t), \quad (1)$$

where A_{LTD} is the amplitude for depression.

For the LTP part, the temporal evolution of the presynaptic low-pass filter $\bar{x}_i(t)$ is described by (see Fig. 5a, trace pre):

$$\tau_+ \frac{d}{dt} \bar{x}_i(t) = -\bar{x}_i(t) + X_i(t),$$

where X_i is the spike train defined above. The quantity $\bar{x}_i(t)$ could, for example, represent the amount of glutamate bound to postsynaptic receptors (Karmarkar and Buonomano 2002; Pfister and Gerstner 2006) or the number of NMDA receptors in an activated state (Senn et al. 2001). The potentiation is then described by the following equation (see Fig. 5a):

$$\frac{d}{dt} w_i^+ = +A_{\text{LTP}}(w_i^+) Y(t) \bar{x}_i(t). \quad (2)$$

where A_{LTP} is the amplitude for potentiation.

There are several implementations of pair-based STDP models. For example, the pre- and postsynaptic traces can consider either all the spikes, i.e., all-to-all interactions (Fig. 5e), or only the nearest neighbor spike (Fig. 5f). Since

Long-Term Plasticity, Biophysical Models, Fig. 4

(continued) postsynaptic spike is constant (pre-post (black), post-pre (gray)), but the frequency of the pairings varies. Pre-post at low frequency does not lead to any weight change, whereas increasing frequency allows for potentiation. (Figure redrawn from Sjöström et al. 2001).

(e) Weak tetanus stimulation. Few extracellular high-frequency trains stimulated presynaptic yield LTP that lasts 2–3 h. (f) Strong tetanus stimulation. If longer high-frequency trains are induced, the potentiation is stable for longer than 10 h. (Figure redrawn from Sajikumar and Frey 2004a)

Long-Term Plasticity, Biophysical Models, Fig. 5 Different types of models. (a) LTP with standard STDP model. The synaptic weight is potentiated at the time of the postsynaptic spike by an amount corresponding to the presynaptic trace. (b) LTD with standard STDP model. The synaptic weight is depressed at the time of the presynaptic spike by an amount corresponding to the postsynaptic trace. (c) LTP with the minimal triplet rule (Pfister and Gerstner 2006). The synaptic weight is potentiated at the

time of the postsynaptic spike by an amount corresponding to the product of a presynaptic and a postsynaptic trace. (d) LTD with triplet rule. Same as standard STDP model. (e) All-to-all interaction of spikes. The trace jumps by a fixed amount when a spike occurs and decays otherwise, leading to cumulative effect from all the previous spikes. (f) Nearest-neighbor interaction of spikes. The trace jumps to a fixed value when a spike occurs and decays otherwise. Only the last spike affects the trace

the synaptic weight cannot grow indefinitely, STDP models add bounds. Additive STDP has hard bounds, i.e., there is a hard cutoff at a minimal and maximal weight value. Multiplicative STDP has soft bounds, and therefore the amount of plasticity depends on the actual synaptic strength (Gütig et al. 2003; Kistler and Leo van Hemmen 2000; Rubin et al. 2001; van Rossum et al. 2000) (see experimental findings on weight dependence (Bi and Poo 1998; Turrigiano and Nelson 2004)). Models of STDP also can take into account homeostasis (Clopath et al. 2010; Kempster et al. 1999; Pfister and Gerstner 2006; van Rossum et al. 2000) (see Turrigiano and Nelson 2004 for experiments).

These types of models can reproduce the spike-timing-dependent learning window (see Fig. 4c), but not the pairing frequency dependence (see Fig. 4d) nor the voltage clamp experiment (see Fig. 4a; Markram et al. 1997; Sjöström et al. 2001). Therefore, nonlinear models were developed to describe those experiments, where triplet interaction of spikes (Clopath et al. 2008, 2010;

Pfister and Gerstner 2006; Senn et al. 2001) (see below) or discount factors on the “efficacy” of successive spikes are considered, similar to including a model of short-term plasticity (Froemke and Dan 2002, model based on extracellular inductions of triplets of spikes).

Triplet Model

The minimal triplet model (Pfister and Gerstner 2006) describes depression the same way as the standard pair-based models. However, potentiation takes into account triplet interactions of spike, two postsynaptic spikes and one presynaptic spike (see Fig. 5c). The model defines a second type of postsynaptic trace $\bar{y}_2$ that decays with a time constant τ_2 , typically on the order of 100 ms. This second trace might represent calcium concentration at the synapse. The synapse is potentiated at the postsynaptic spike time by an amount that is proportional to the product of the presynaptic spike trace $\bar{x}_i(t)$ (see Fig. 5c, trace pre) and the second postsynaptic spike trace $\bar{y}_2$ (see Fig. 5c, trace post 2). The potentiation is written:

$$\frac{d}{dt}w_i^+ = +A_{\text{LTP}}(w_i^+)Y(t)\bar{x}_i(t)\bar{y}_2(t), \quad (3)$$

where A_{LTP} is the amplitude for potentiation.

This model is able to reproduce the frequency experiment (see Fig. 4d), but not the voltage clamp experiment (see Fig. 4a), since it only depends on the spike timing, and not on the postsynaptic membrane potential.

Models Based on Spike Timing and Postsynaptic Voltage

Voltage-based models (Abarbanel et al. 2002; Brader et al. 2007; Clopath et al. 2010) typically depend on the presynaptic spike time and on the postsynaptic voltage. We describe here one voltage-based model in more detail.

Voltage-Triplet Model

The voltage-based-triplet model (Clopath and Gerstner 2010; Clopath et al. 2008, 2010) is designed to reproduce the frequency experiment (see Fig. 4d) and the voltage clamp experiment (see Fig. 4a; Clopath et al. 2008). The rule is written as.

$$\begin{aligned} \frac{d}{dt}w_i = & -A_{\text{LTD}}X_i(t)[\bar{u}_-(t) - \theta_-]_+ \\ & + A_{\text{LTP}}[u(t) - \theta_+]_+\bar{x}_i(t)[\bar{u}_+(t) - \theta_+]_+, \end{aligned} \quad (4)$$

where u is the postsynaptic voltage, $\bar{u}_{+/-}$ are postsynaptic voltage low-pass filters with two different time constants, $\theta_{+/-}$ are thresholds, and $[x]_+$ is x when $x > 0$ and 0 otherwise. It was shown to reproduce a large part of the experimental literature on long-term plasticity (Clopath and Gerstner 2010), such as spike-timing pair, burst, triplet and quadruplet experiments (Bi and Poo 1998; Froemke and Dan 2002; Markram et al. 1997; Nevian and Sakmann 2006; Wang et al. 2005), frequency dependence (Dudek and Bear 1992; Markram et al. 1997; Sjöström et al. 2001), voltage clamp experiments (Artola et al. 1990; Ngezahayo et al. 2000), and dendritic dependency (Sjöström and Häusser 2006). This model has very different functional implications in networks than pair-based rules (Clopath et al. 2010).

Models Based on Receptor Dynamics

Those models describe typically glutamate binding, AMPA receptors (Saudargiene et al. 2003), or NMDA receptors (Gamble and Koch 1987; Holmes and Levy 1990; Senn et al. 2001; Zador et al. 1990).

Senn-Tsodyks-Markram Model

The Senn-Tsodyks-Markram (STM) model (Senn et al. 2001) takes into account the dynamics of the NMDA receptor. The receptors can be in three different states: rest, up, or down. In the absence of spikes, NMDA receptors are in the rest state, but they can be upregulated when a presynaptic spike occurs or downregulated at the postsynaptic spike time. A notion of two types of second messengers is introduced in the model, so that when a postsynaptic spike occurs, second messenger type 1 can be upregulated only if the NMDA receptors are in the up states already. Conversely, the second messenger type 2 can be downregulated if there is a presynaptic spike and if the NMDA receptors are already in the down state. Finally, LTP is elicited when there is a postsynaptic spike and the second messenger type 1 is in the up state; LTD occurs at the time of a presynaptic spike if the second messenger type 2 is downregulated. This model takes into account pair interaction of spikes and triplet interactions of spikes, i.e., one presynaptic spike, two postsynaptic ones for potentiation, and two presynaptic and one postsynaptic spike for depression.

It reproduces frequency dependence experiment (see Fig. 4d), as well as STDP experiment (see Fig. 4c), but not the voltage clamp experiment (see Fig. 4a). It can be mapped to the BCM rule although the depression term is not linear in the presynaptic term.

Models Based on Calcium

There are several models depending on calcium concentration (Abarbanel et al. 2003; Badoual et al. 2006; Cai et al. 2007; Froemke et al. 2005; Karmarkar and Buonomano 2002; Karmarkar et al. 2002; Lisman 1989; Rubin et al. 2005; Shouval et al. 2002); two are described here in more detail.

Shouval Model

The calcium model of Shouval et al. (2002) takes the concentration of calcium in the postsynaptic cell as a measure for plasticity. Low calcium concentration is not affecting the synapse, intermediate concentration leads to LTD, and high concentration leads to LTP. The model describes the calcium changes at the synapse: the calcium current flows through the NMDA receptors only if the presynaptic spike is paired with a back-propagating action potential.

It reproduces the voltage clamp experiment (see Fig. 4a), presynaptic stimulation frequency experiment (see Fig. 4b), and the STDP experiments (see Fig. 4c). However, it predicts a LTD part in the pre-post side of the STDP curve due to the shape of the back-propagating action potential. Refinements of this model are proposed in Shouval and Kalantzis (2005).

Graupner Model

In the calcium model of Graupner and Brunel (2012), potentiation and depression are activated by calcium thresholds, where presynaptic and postsynaptic action potentials elicit calcium transients. The synapses are considered to be bistable. The model gives rise to a multiple of learning curves and reproduces the frequency dependence (see Fig. 4d). This model is a simplified version of a more detailed biophysical model (Graupner 2008).

Models Based on CaMKII

Bistable Models

Bistable models (Lisman 1985) were introduced as a solution to the following paradox: since the molecular turnover is fast, on the order of minutes to hours, how can the synapses keep their strength for much longer? The idea was that the CaMKII can switch between a phosphorylated and unphosphorylated state (Lisman 1985, 1989; Okamoto and Ichikawa 2000; Zhabotinsky 2000). Mathematical models of CaMKII phosphorylation and dephosphorylation show a bistability regime (see, e.g., (Lisman and Zhabotinsky 2001; Miller et al. 2005; Zhabotinsky 2000), although some don't find bistability mathematically (Kubota and Bower

2001) and in the experiments (Bradshaw et al. 2003)). These models have a number of limitations concerning the number of molecules involved (Miller et al. 2005) and CaMKII trafficking (Hayer and Bhalla 2005). Finally, although the importance of CaMKII for the induction of plasticity is clearly demonstrated, some experimental studies suggest that CaMKII is not involved for the maintenance of plasticity (late-phase consolidation) (Malinow et al. 1989; Othmakhov et al. 1997).

There are alternative models for the maintenance of plasticity, such as a bistability of translational switch (Blitzer et al. 2005), a cluster model of AMPA receptors (Shouval 2005), and memory reactivation model (Smolen 2007; Wittenberg et al. 2002). For models of kinases and phosphates, refer to (Abarbanel et al. 2003; Ajay and Bhalla 2004; Castellani et al. 2005).

Bistable Biophysical Models and Spike Timing

These models (Graupner and Brunel 2007; Urakubo et al. 2008) describe how precise spike timing induces a calcium transient. The resulting calcium concentration influences the CaMKII bistable system: at low concentration, up and down states are stable; at medium concentration, only the down state is stable; and at high calcium concentration, only the up state is stable. The model reproduces the different spike-timing-dependent plasticity experiments, and the bistable CaMKII system allows stable synapses.

Consolidation Models

Synaptic tagging experiments (Frey and Morris 1997) reveal two phases of long-term synaptic plasticity: the early phase, which induces a change that lasts 2–3 h (Fig. 4e), and the late phase, which lasts more than 10 h (Fig. 4f). Standard STDP models and detailed biophysical models don't discriminate and only describe the induction of plasticity, assuming the changes to be long lasting. Below, models of synaptic consolidation are explained in detail.

Cascade Model

The cascade model (Fusi et al. 2005) is designed to optimize the memory lifetime. It proposes a bistable synapse that can either take a weak or a strong value.

For each value, the synapse can be in different plastic states, called “metastates.” For example, if the synapse is already weak and undergoes a LTD protocol, it will keep the same weak value but will go to a lower metastate, where the synaptic weight is harder to change, i.e., less plastic.

Models of Synaptic Tagging

There are currently two models describing the late phase of long-term plasticity.

The TagTriC model (Clopath et al. 2008) is separated into three processes:

1. **Tagging:** The synapse strength is the sum of two parts, the weight of the early phase and the weight of the late phase. The early weight is a stochastic three-state variable (O’Connor et al. 2005; Petersen et al. 1998); it can be in neutral state, high state, or low state. If the early weight is in the high or low state, it is automatically tagged. The state of the early weight switches from neutral to high or low with a probability given by a Hebbian rule for the induction of plasticity (Clopath et al. 2008, 2010). It decays back to neutral with a certain transition probability.
2. **Trigger:** If the number of tags exceeds a threshold, plasticity-related proteins are synthesized. The threshold depends on the dopamine level, such that if dopamine is high, the threshold is lowered. Extracellular stimulation also stimulates dopaminergic fibers, lowering the threshold.
3. **Consolidation:** The late weight of the synapse is a continuous variable with two stable states. If plasticity-related proteins are available and if the synapse is tagged, the late weight can switch to a different stable state, thus allowing for consolidation.

This model can reproduce the synaptic tagging experiment (Fig. 4e, f), as well as several pharmacological experiments (Frey and Morris 1997; Sajikumar and Frey 2004a).

The consolidation model of Barrett et al. (2009) is very similar to TagTriC (Clopath et al. 2008), with some differences in its implementation. A synapse has one of two states (weak or low),

but each state additionally has one of three meta-states: early phase, tagged, or consolidated. As in TagTriC, synapses are stochastic, and their synaptic weight is a compound of several synapses. The transitions between states are a function of the protocol (weak tetanus or strong tetanus). Thus, induction of plasticity is not modeled explicitly nor is a mechanism of plasticity-related proteins synthesis designed, in contrast to the TagTriC model. However, the model dissociates the tag state from early-phase state, which is supported by the experiments where tags are reset (Sajikumar and Frey 2004b), experiments that are not directly captured by the TagTriC model.

Sources and Further Readings

This text is based on the introduction of Clopath (2009, 2012). For further readings, refer to the reviews on biophysical models (Graupner and Brunel 2010) (and the Chap. 2.7.2–4 of Graupner 2008), on phenomenological models of STDP (Morrison et al. 2008), on models and experiments of STDP (Feldman 2012), and synaptic consolidation (Clopath 2012), as well as the Scholarpedia articles (Shouval 2007, 2009; Sjoestrom and Gerstner 2010).

Definition

Low-voltage-activated (LVA) calcium channels are a class of voltage-gated calcium (Ca^{2+}) channels that exhibit a high probability of opening at hyperpolarized membrane voltages (negative to -50 mV). LVA channels consist of a Cav3 family, of which there are three isoforms (Cav3.1 ([α1G](#)), 3.2 ([α1H](#)), 3.3 ([α1I](#))). Cav3 channels exhibit a low single-channel conductance and rapid inactivation, resulting in “tiny” and “transient” currents, often termed T-type current or I_T . T-type calcium channels were first recognized for their contribution to burst depolarizations and pacemaker activity in specific neurons but are now known to influence a wide range of cell outputs (Huguenard [1996](#); Perez-Reyes [2003](#); Yunker and McEnery [2003](#)).

Detailed Description

Several families of Ca^{2+} channels are expressed in neurons, which can be broadly classified in two groups based on voltage dependence. High-voltage-activated (HVA) Ca^{2+} channels show significant activation at potentials positive to -30 mV and include the L-type (Cav1), P-/Q-type (Cav2.1), N-type (Cav2.2), and R-type

(Cav2.3) channels. Low-voltage-activated (LVA) Ca^{2+} channels are activated at hyperpolarized potentials 20–30 mV more negative than HVA channels and are comprised solely of the Cav3 family of channels (although some L-type isoforms (Cav1.3, Cav1.4) do exhibit relatively low-voltage dependence). Cav3 channels have a small single-channel conductance of only ~ 1.7 pS in 2 mM $[\text{Ca}^{2+}]_o$ and 9 pS in 10 mM $[\text{Ba}^{2+}]_o$ (Weber et al. 2010).

Distribution of LVA Ca^{2+} Channels

To date, three Cav3 isoforms (Cav3.1–Cav3.3) have been discovered and all are prominently but differentially expressed throughout the CNS, including the cortex, hippocampus, thalamus, and cerebellum (Craig et al. 1999; Talley et al. 1999; McKay et al. 2006). Each isoform can be expressed as a variety of splice variants, increasing the variation of expression of Cav3 channels.

Quantification of Voltage Dependence

All Cav3 channel isoforms and splice variants exhibit significant activation at hyperpolarized voltages that can be detected below threshold for spike discharge in neurons, with half-activation voltages ranging from -40 to -75 mV (although Cav3 channels do show activation from as low as -90 mV (Engbers et al. 2012)) (Fig. 1). Cav3 channels also exhibit rapid inactivation upon depolarization with a half-inactivation voltage ranging from -90 to -60 mV (Fig. 1). The inactivation time constant decreases with increased depolarization (Fig. 1a), but unlike Cav1 channels that exhibit Ca^{2+} -dependent inactivation via binding of calmodulin, T-type inactivation is inherent to the channel and Ca^{2+} independent.

A unique aspect of Cav3 channels is an overlap of activation and inactivation curves that provides a “window” current between -70 and -20 mV, where a small percentage of channels remains in the active state (Fig. 1b). This window current provides continual Ca^{2+} influx at subthreshold potentials and may comprise only 2% of total

available current yet is sufficient to markedly affect neuronal firing (Huguenard 1996; Perez-Reyes 2006; Engbers et al. 2012). The size of the window current depends critically on the extent of overlap of Cav3 voltage for activation and inactivation, with a resulting cell-to-cell variation depending on the biophysical properties of Cav3 channels (Dreyfus et al. 2010). The role for Cav3 window current in controlling membrane excitability must then be assessed carefully in individual cell classes.

Modeling LVA Calcium Channels

T-type channel kinetics can be modeled using the Hodgkin-Huxley formalism with both activation and inactivation variables being described by Boltzmann functions (Fig. 1b). Steady-state voltage relationships are then described by the equation:

$$m_{\infty} = \frac{1}{1 + e^{\frac{-(V - V_a)}{k}}}$$

where m is the gating variable, V_a is the half-(in) activation voltage that satisfies $m_{\infty}(V_a) = 0.5$, and k is the slope factor which is positive for activation and negative for inactivation. The gating variables move toward the steady-state values as $t \rightarrow \infty$ according to the differential equation:

$$\frac{dm}{dt} = \frac{m_{\infty} - m}{\tau_m}$$

where τ_m is the gating time constant. Parameters for half-activation and inactivation voltages, as well as slope factors and time constants, have been determined experimentally and tabulated previously (Huguenard 1996; Ifinca et al. 2006). T-type channel gating can also be modeled with Markov state models (Chen and Hess 1990; Burgess et al. 2002).

Once a model with suitable parameters has been chosen, LVA Ca^{2+} current (I_{CaT}) is described by the equation:

$$I_{CaT} = g_{CaT} \cdot m \cdot h \cdot (V - E_{Ca})$$

Low-Voltage-Activated Calcium Channels,

Fig. 1 Illustration of Cav3 activation and inactivation properties.

(a) Simulated LVA Ca^{2+} current based on a published model (Chen and Hess 1990). The model was held at -100 mV and voltage was increased in 10 mV steps (bottom). Currents are detected by -60 mV (red), with increased depolarization resulting in larger currents and faster inactivation, resulting in a transient current that exhibits a “crossover” at higher levels of depolarization due to the voltage dependence of inactivation. (b) Activation (black) and inactivation (red) plots of Cav3 channels exhibit an overlap to create a “window” current that straddles resting potential and spike threshold where Cav3 channels are constitutively active

where g_{CaT} is the conductance density of Cav3 channel, m and h are activation and inactivation gating variables, respectively, and E_{Ca} is the reversal potential for Ca^{2+} . It is important to note that differential permeabilities to Ca^{2+} and K^{+} ions cause the reversal potential for T-type current to deviate from the predicted Nernst potential of ~ 130 mV to a less polarized value of ~ 40 mV. Moreover, it is becoming increasingly common to model Ca^{2+} currents using Goldman-Hodgkin-Katz current equations; in this case the conductance density has to be replaced by a permeability.

Functions of LVA Calcium Channels

LVA current can generate a “low threshold spike” which leads to burst generation, such as that seen

in thalamic (Jahnsen and Llinas 1984) and cerebellar nuclear neurons (Jahnsen 1986; Molineux et al. 2006). Through interplay with other subthreshold currents, such as hyperpolarization-activated current (I_{H}), LVA current can generate pacemaker activity in neurons. The voltage-dependent inactivation of Cav3 channels can also give rise to multiple spiking modes, as seen for thalamocortical neurons, where tonic firing is observed at depolarized potentials that inactivate Cav3 channels and a burst firing mode at hyperpolarized potentials that deinactivate Cav3 channels.

Subthreshold activation allows Cav3 channels to affect synaptic integration, such as amplifying subthreshold excitatory postsynaptic potentials (Magee and Johnston 1995). While long believed to function in isolation, recent work indicates that

Cav3 channels can associate with both Ca^{2+} - and voltage-gated K^{+} channels to regulate cell output (Turner et al. 2011; Engbers et al. 2012; Rehak et al. 2013; Anderson et al. 2010). For reviews on LVA channel function, see the “References” section.

Definition

A model of a mammalian motor nerve fiber is a mathematical description of the electrochemical events taking place during the initiation and propagation of an action potential in a peripheral nerve fiber. This description accounts for the movement

of ions through protein channels (conductances) embedded in the axon membrane. These channels are differentially distributed along different regions of the nerve fiber (e.g., node of Ranvier vs. internode) and have different conduction properties (e.g., fast sodium, persistent sodium, or slow potassium conductances).

Detailed Description

Anatomical Considerations

The cell body of a mammalian motor fiber resides in the ventral grey matter of the spinal cord or in the brainstem and projects its axon through a peripheral or cranial nerve that innervates its final target: the muscle fiber. The axonal

diameter of a mammalian α -motor neuron that innervates extrafusal muscle fibers typically falls between 9 and 20 μm (Eccles and Sherrington 1930). Additionally, its conduction velocity (speed at which it propagates an action potential) is approximately 6 m/s per μm of diameter (Hursh 1939). The axon of a motor fiber is predominantly covered by Schwann cells, which form a myelin sheath (Fig. 1a). At regular intervals of about 100 times the fiber diameter, however, the underlying axonal membrane is exposed at the nodes of Ranvier. These nodes exhibit a high concentration of certain ionic channels, particularly channels that conduct sodium in the mammalian fiber, and therefore most of the active conduction occurs at the nodes (saltatory propagation).

Mammalian Motor Nerve Fibers, Models of, Fig. 1 Modeling a mammalian motor fiber. (a) Diagram of a myelinated fiber showing the myelin sheath, mostly covering the axon except at the nodes of Ranvier, and protein channels embedded in the axolemma (axon membrane). The distinct segments of the fiber are also illustrated: node, paranode, juxta-paranode, and internode. (b) Double cable model of a mammalian myelinated fiber

showing a node connected to an internodal segment through an axoplasmic conductance (G_a) and to a myelin segment through a periaxonal conductance (G_p). (c) Electrical circuit equivalent model of the node of Ranvier used in McIntyre et al. (2002), including a linear leakage (L_k), fast (Na_f) and persistent (Na_p) sodium, and slow potassium (K_s) conductances, in parallel with the membrane capacitance (C_n)

Cable Model

The flow of ions (charges) involved in the initiation and propagation of an action potential can be calculated with electrical circuit equivalent models that account for the membrane capacitance (phospholipid bilayer) and the resistance or conductance of individual ionic channels (Fig. 1b, c). A short length or “patch” of nerve fiber membrane constitutes a compartment, which can be assembled in series with other compartments to represent a section or an entire fiber. In a myelinated fiber, each node of Ranvier can be represented as a single nodal compartment. In addition, if myelin acts as an electrical insulator, then consecutive nodal compartments can be coupled with single resistors. These resistors represent the intracellular conduction between nodes along the length of axon under the myelin. However, more comprehensive representations include a finite impedance myelin sheath attached to internodal compartments (Halter and Clark 1991). Furthermore, since the fiber morphology appears to play an important role in the threshold fluctuations following an action potential (recovery cycle), specific segments including the belt of myelin attachment and the paranodal region can be explicitly represented. Hence, a double cable model has been proposed in which the internodal segments are composed of the myelin sheath and the internodal axolemma (Fig. 1b) (Stephanova and Bostock 1995; Richardson et al. 2000; McIntyre et al. 2002).

Membrane Dynamics

Each compartment of the cable model represents the electrochemical properties of the associated membrane patch. First, since the phospholipid bilayer membrane acts as a dielectric separating two conductive media, it can be modeled as a capacitor. Secondly, the differences in concentrations of each ion between the intracellular and extracellular spaces (i.e., across the membrane) give rise to a transmembrane voltage difference that can be modeled with batteries representing the Nernst potential of each of the contributing ions. Finally, the protein channels embedded in

the membrane that allow passage of ions can be modeled with resistors. Under low-amplitude stimulation (below threshold), the ionic conductances (resistors) are represented with linear models. In this case, the membrane passively conducts current and no action potential occurs. However, larger stimuli (above threshold) can drive the membrane to conduct actively ionic currents. In this situation, the ionic conductances are better described by nonlinear models. According to the Hodgkin and Huxley (1952) formulation, the conductance of an ionic channel equals the maximum conductance multiplied by one or more gating variables. It follows that each gating variable, u , evolves according to the differential equation $du/dt = \alpha(1 - u) - \beta u$, where the parameters α and β are estimated empirically and usually vary with the transmembrane voltage.

In mammalian peripheral fibers, different types of sodium channels as well as slow voltage-gated potassium channels tend to concentrate in the node of Ranvier, whereas other potassium channels, cation channels, and calcium channels, as well as certain pumps and exchangers, concentrate in the paranode and internode (Krishnan et al. 2009). Consequently, models of mammalian motor fibers have represented the nodal compartments with fast (Na_f) and persistent (Na_p) sodium and slow potassium (K_s) conductances (e.g., Schwarz et al. 1995; McIntyre et al. 2002; Howells et al. 2012, who also added a fast potassium conductance), although models with a single sodium conductance have also been proposed (e.g., Chiu et al. 1979; Sweeney et al. 1987).

Recovery Cycle

Following an action potential, axons exhibit absolute and relative refractory periods, where they are less susceptible to re-excitation, followed by periods of decreased (supernormality) and increased (subnormality) thresholds that are associated with oscillations in the transmembrane voltage, termed depolarizing (DAP) and hyperpolarizing (AHP) afterpotentials, respectively. This sequence of changes in excitability following an action potential constitutes the recovery cycle

of axons. Models of motor fibers have illuminated the mechanism of the recovery cycle by incorporating more accurate geometrical and electrical descriptions of the axon. For instance, the double cable model of McIntyre et al. (2002) suggested that both persistent sodium current and passive discharge through the paranodal seal resistance contributed to the DAP, whereas AHP was mediated by slow potassium channels.

Difference with Sensory Fibers

Motor and sensory fibers differ in action potential shape, recovery cycle, and excitability properties (Howells et al. 2012). The mechanisms underlying these differences may be determined using fiber-type-specific models. For example, McIntyre et al. (2002) argued that the smaller supernormality of sensory fibers could be attributed to the kinetics of the sodium conductances rather than the density of these channels in the node. Specifically, they found that slowing the fast sodium channels resulted in reduced supernormality, which is consistent with experimental findings in sensory fibers. Similarly, both the duration and amplitude of the supernormal period decreased with faster sodium channel inactivation. Moreover, Howells et al. (2012) proposed that an increased expression of the fast isoform of the hyperpolarization-activated cyclic-nucleotide gated (HCN) channel could participate in limiting hyperpolarization in sensory fibers. Additionally, their model suggested that a reduced expression of slow potassium channels in the node of sensory fibers and the concomitant depolarization of resting membrane potential could be responsible for the broader action potential in these fibers. Taken together, these findings emphasize that dynamical and structural considerations can lead to more accurate models of functionally distinct fibers.

Definition

A Markov model is a simplified phenomenological representation of (bio)physical, chemical, or biological process dynamics, described quantitatively as a set of discrete states and by the ease of transition through time from one state to another.

In chemistry, for instance, a complex reaction can be represented as a kinetic scheme, although ultimately it occurs from the rearrangement of

electrons in the bonds between atoms, according to the laws of quantum physics. Nonetheless, for most practical purposes, the changes of the reactants' concentration and their equilibria can be effectively predicted by a reduced kinetic description, involving simple concepts such as affinity, valence, and reaction rates.

In the context of modeling the ionic permeability of a protein channel and the activation of a (synaptic) membrane receptor, of a transporter, of a second messenger, or of the activity-dependent short-term synaptic plasticity (Destexhe et al. 1998; Yamada et al. 1998; Tsodyks et al. 1998), Markov models are widely used and defined as a weighted directed graph, such as those in Figs. 1 and 2. Individual nodes of the graph represent the discrete conformational states that the proteins tertiary or quaternary structure may assume at a given time, while the edges represent the possible transitions between states. In addition, a positive (kinetic) coefficient is associated with each edge, representing the frequency (or rate) of occurrence of the corresponding transition in time.

Of course, ion permeation across an excitable biological membrane ultimately depends on a variety of molecular properties, chemical interactions, and electrostatic effects (Johnston and Wu 1994; Hille 2001), including the primary structure of protein channels, their subunits' composition, the charge distribution across their domains, the electrostatic and geometrical properties of their

Markov Models of Ion Channels, Fig. 1 Markov model of a single ion channel, with two possible states: **A** and **B**. In the graph, the transition probabilities between states per unit of time are indicated by α and β , above each edge

Markov Models of Ion Channels, Fig. 2 Markov model of the Hodgkin-Huxley delayed rectifier potassium channel

selectivity filter, their phosphorylation binding sites, the local electric field, and so on. However, reduced phenomenological descriptions by Markov models allow one to understand and predict the evolution in time and the equilibrium of each membrane ionic conductance. For such reasons, Markov models are a versatile tool for modeling the ionic basis of cellular excitability.

We also remark that their description, based on a directed graph, captures an important feature of many – but not all – (bio)physical systems, the Markovian property (Cox and Miller 1965): the occurrence of a transition from a state to another depends only on the currently occupied state and on the transition rates of the edges originating from it, but not on the states occupancy history of the system.

Detailed Description

The most widespread application of Markov models, in the field of computational neuroscience, is the deterministic description of ionic membrane currents across an excitable cell membrane patch (Sterrat et al. 2011). Since these macroscopic currents emerge from the superposition of a large number of microscopic contributions across individual ion channels, we discuss first the dynamics of a single ion channel (Clay and DeFelice 1983; Hille 2001; Colquhoun and Hawkes 2009a). We then introduce the ionic permeability arising from a large population of identical and independent channels, discussing deterministic models of the macroscopic membrane currents. We then briefly discuss numerical methods for the simulation of both stochastic and deterministic versions of Markov models.

Stochastic Description: Single-Channel Dynamics

Let us consider the simplest ion channel: a membrane protein whose three-dimensional conformation has only two possible stable configurations. Therefore, at any given time, the channel can be found only in one of the two states (Fig. 1). We

completely neglect the molecular details underlying those stable configurations, as well as the mechanisms of state transition: we phenomenologically describe the system by naming its states with two abstract labels, **A** and **B**. We also assign to each possible transition its corresponding frequency of occurrence: these are assumed to be known from electrophysiological experiments (Conti and Wanke 1975; Colquhoun and Sigworth 2009; Milesu et al. 2008; Menon et al. 2009), and they have been indicated as α and β in Fig. 1 and have the unit of the inverse of a time.

The weighted graph summarizes the ion channel dynamics by implying a key underlying hypothesis: the transitions from **A** to **B** or from **B** to **A** occur randomly in time as Poisson point processes (Cox and Miller 1965), with parameters α and β , respectively. This can be rephrased equivalently by specifying the unpredictable character of the intervals between two successive random transitions: these intervals, known as the occupancy lifetimes T , are realizations of continuous random variables, with an exponential probability distribution density $f_T(T)$ (Papoulis and Pillail 2002; Colquhoun and Hawkes 2009a):

$$\begin{aligned} f_{T_A}(T) &= \alpha \exp(-\alpha T), & f_{T_B}(T) \\ &= \beta \exp(-\beta T) \end{aligned} \quad (1)$$

We reconcile our intuition with the style of (graphically) placing α and β above each edge in Fig. 1, by deriving the instantaneous transition probabilities. By definition of probability density, and by evaluating Eq. 1 over a very small interval $T = \Delta t$, it follows that

$$\begin{aligned} \text{Prob}\{\mathbf{A} \rightarrow \mathbf{B} \text{ in}[t; t + \Delta t)\} &= f_{T_A}(\Delta t)\Delta t \approx \alpha\Delta t \\ \text{Prob}\{\mathbf{B} \rightarrow \mathbf{A} \text{ in}[t; t + \Delta t)\} &= f_{T_B}(\Delta t)\Delta t \approx \beta\Delta t \end{aligned}$$

where higher-order infinitesimal terms (e.g., Δt^2 , Δt^3) have been ignored in the Taylor series expansion around $T = 0$, for each exponential function.

These transition probabilities, together with the initial occupancy (probability) conditions, fully describe the dynamics of the ion channel during both transients and steady state. In fact, the time-varying marginal probabilities of occupancy of

each state at time t , $P_A(t)$ and $P_B(t)$, can be readily computed from α and β and from the above hypotheses. To this aim, we consider an infinitesimal interval $[t; t + dt)$ and express the probability of observing the ion channel in a state (e.g., **A**) at $t + dt$, in terms of the same probability at t . This is equivalent to the conjunction and disjunction of four independent events, expressed by the known quantities: observing the ion channel in **A** at t and having no transition **A** $\rightarrow$ **B** during $[t; t + dt)$ or observing the ion channel in **B** at t and having a transition **B** $\rightarrow$ **A** during the same time interval. Formally, we can write two equations,

$$\begin{aligned} P_A(t + dt) &= P_A(t)(1 - \alpha dt) + P_B(t)\beta dt \\ P_B(t + dt) &= P_B(t)(1 - \beta dt) + P_A(t)\alpha dt \end{aligned}$$

which, in the limit $dt \rightarrow 0$, become a homogeneous system of linear ordinary differential equations, known as the Kolmogorov equations:

$$\begin{aligned} \frac{d}{dt}P_A(t) &= -\alpha P_A(t) + \beta P_B(t) \\ \frac{d}{dt}P_B(t) &= \alpha P_A(t) - \beta P_B(t) \end{aligned}$$

By matrix notation, these equations can be rewritten in compact form as

$$\frac{d}{dt}\mathbf{P} = \mathbf{Q}\mathbf{P} \quad (2)$$

by defining the (column) probability vector $\mathbf{P}$ and the (square) matrix $\mathbf{Q}$, known as *generator* matrix of the Markov model:

$$\mathbf{P} = \begin{pmatrix} P_A \\ P_B \end{pmatrix}, \quad \mathbf{Q} = \begin{pmatrix} -\alpha & \beta \\ \alpha & -\beta \end{pmatrix}$$

Solving Eq. 2 by analytical or numerical methods (see section “[Deterministic Simulations: Numerical Methods](#)”) gives a complete description of the system, as $\mathbf{P}(t)$ fully reveals statistically its state occupancies at any time t .

Of course, in most cases, a simple two-state kinetic scheme as that of Fig. 1 is not sufficient to model the dynamics of a generic ion channel. Nevertheless, Eq. 2 is a general formulation of the temporal evolution of the statistical occupancy of any Markov model. For kinetic schemes of arbitrary complexity with n states, the probabilities of occupancy at time t are still the solution of the system of n equations, formally Eq. 2, with an appropriate $n \times n$ generator matrix.

For instance, the voltage-gated delayed rectifier potassium channel (Hille 2001) of the Hodgkin-Huxley description of the squid giant axon excitability (Hodgkin and Huxley 1952) is best described by $n = 5$ states and 8 transitions, out of the $n(n - 1) = 20$ theoretically possible (Fig. 2). In this case, the scheme of Fig. 2 has a probability vector $\mathbf{P}$ and a generator matrix $\mathbf{Q}$, can be defined and derived as in the two-state model, and is given by

$$\mathbf{P} = \begin{pmatrix} P_A \\ P_B \\ P_C \\ P_D \\ P_E \end{pmatrix}, \quad \mathbf{Q} = \begin{pmatrix} -4\alpha & \beta & 0 & 0 & 0 \\ 4\alpha & -(3\alpha + \beta) & 2\beta & 0 & 0 \\ 0 & 3\alpha & -(2\alpha + 2\beta) & 3\beta & 0 \\ 0 & 0 & 2\alpha & -(\alpha + 3\beta) & 4\beta \\ 0 & 0 & 0 & \alpha & -4\beta \end{pmatrix}$$

We further remark that the transition rates, combined together as elements of $\mathbf{Q}$, can be in general positive functions of time or of any external variable that controls the channel dynamics (e.g., the membrane potential for voltage-gated ion channels or the concentration of a ligand for

ligand-gated ion channels). In this case, a closed-form analytical solution of Eq. 2 may not be available. We also note that, by definition, the occupancy probabilities sum to 1 (e.g., $P_A + P_B + \dots + P_E = 1$), so that given a kinetic scheme with n states, only $n - 1$ equations of Eq. 2 are

independent. Equivalently, the generator matrix $\mathbf{Q}$ always has at least one null eigenvalue.

We conclude this subsection by adding that no assumption has been made on the reversibility of the transition between any connected pair of states. At the thermodynamical equilibrium, it might be argued that the molecular mechanisms underlying the state transitions must obey a microscopic reversibility principle (Colquhoun and Hawkes 2009a). For the purpose of this review, Markov models have been considered as phenomenological abstract descriptions without accounting for any further microscopic details of channel gating. For instance, strongly asymmetric Markov models may still occur when the microscopic mechanisms are coupled to a source of energy (Colquhoun and Hawkes 2009a). Nonetheless, in the context of experimental identification of the parameters of a Markov model (Conti and Wanke 1975; Colquhoun and Sigworth 2009; Milesu et al. 2008; Menon et al. 2009), imposing constraints for the scheme reversibility might of course be advantageous as it reduces the number of free parameters (Colquhoun and Sigworth 2009).

Stochastic Description: Single-Channel Currents

Relating the ionic currents through a cell membrane patch to single-channel configurations is now mathematically straightforward. For simplicity, we discuss the case in which only one *open* state exists, among the n states of its kinetic scheme. Such a conformational state is the only one to have a nonzero electrical conductance, and we refer to such a value as γ (with typical values ≈ 1 –50 pS). We conventionally rename this state as **O** (e.g., corresponding to the state **B** in Fig. 1 or to the state **E** in Fig. 2), and we associate a (Bernoulli) random variable ξ to it, taking at time t the value 1 with probability $P_{\mathbf{O}}(t)$ or 0 with probability $1 - P_{\mathbf{O}}(t)$: $\xi(t)$ is then a stochastic process of time, with discrete (i.e., binary) values.

We note that, in the context of the matrix notation introduced earlier, $P_{\mathbf{O}}(t)$ can be concisely referred to the solution of Eq. 2, as $P_{\mathbf{O}}(t) = \mathbf{R}\mathbf{P}$, by the definition of an ad hoc (row) vector $\mathbf{R}$. This

vector has the same number of elements as $\mathbf{P}$, but all of them are identically zero except for the entry in the position corresponding to the **O** state, which is set to 1. For instance, referring to **O** as the state **B** in the scheme of Fig. 1 implies defining $\mathbf{R} = [0 \ 1]$, while as the state **E** in Fig. 2 implies defining $\mathbf{R} = [0 \ 0 \ 0 \ 0 \ 1]$.

Then, the ionic conductance of a single channel is also a Bernoulli random variable for each time t , $g_1(t) = \chi\xi(t)$, which can take either the value 0 or γ . When N identical and independent ion channels operate in parallel within the same membrane patch, we describe each channel by an identical Markov model and we associate to each of them an independent variable $\xi_k(t)$, $k = 1, 2, 3, \dots, N$, as defined before. The resulting overall conductance of the membrane patch is assumed to be the linear superposition of individual contributions, $g_N(t)$ is a stochastic process taking discrete random values γ , or 2γ , or 3γ , ..., or up to a maximal value $\bar{g} = N\gamma$, following a binomial probability distribution (Papoulis and Pillai 2002).

Under the common *ohmic* approximation (Sterrat et al. 2011), the ionic currents of a single channel $I_1(t)$ or of a population of N identical channels $I(t)$ are given by

$$\begin{aligned} I_1(t) &= g_1(t)(E_x - V_m(t)) \\ I(t) &= g_N(t)(E_x - V_m(t)) \end{aligned} \quad (3)$$

where E_x is the Nernst-Planck equilibrium potential for the ionic species x the channels are selectively permeable to (e.g., $x \in \{Na^+, K^+, Cl^-, Ca^{2+}\}$). Finally, $V_m(t)$ represents the transmembrane electrical potential of the membrane patch.

Introducing a precise motivation for the deterministic formulation of Markov models, discussed next for large populations of identical channels, we report below the ensemble mean and variance of $g_N(t)$ (Conti and Wanke 1975), indicating by $E\{\cdot\}$ the expected value:

$$E\{g_N(t)\} = \bar{g}P_{\mathbf{O}}(t) \quad (4)$$

$$\text{Var}\{g_N(t)\} = N^{-1}\bar{g}P_{\mathbf{O}}(t)(1 - P_{\mathbf{O}}(t)) \quad (5)$$

We observe that the variance decreases for increasing values of N . Therefore, by the law of

Markov Models of Ion Channels, Fig. 3 Numerical stochastic simulations of a step change in the transition rates of potassium (*left column*) and sodium (*right column*) Hodgkin-Huxley voltage-gated channels, obtained for increasing number of identical channels within the same membrane patch. The step is applied as a voltage step,

occurring at time $t = 0$ and ranging from -65 to -25 mV. The *black lines* are realizations of the stochastic process underlying channel dynamics (Eq. 3), while the *orange trace* is obtained as Eq. 4, solving numerically Eq. 2

large numbers (Papoulis and Pillail 2002), one may replace the stochastic temporal evolution of $g_N(t)$ by its ensemble mean $E\{g_N(t)\}$ for large N (e.g., in the hundreds or thousands), effectively ignoring the random fluctuations which are intrinsically associated to single-channel permeability. To better clarify this important point, we report the numerical simulations of the open-state dynamics of a population of N Hodgkin-Huxley fast-inactivating sodium ion channels or delayed rectifier potassium ion channels (as in Fig. 2) (Hodgkin and Huxley 1952). Both channel types are described by Markov models, with

kinetic rates that change as a function of V_m (Sterrat et al. 2011; Hille 2001). Figure 3 displays as black traces the realizations of the process $g_N(t)$, normalized to its maximal possible value $\bar{g}$. Such a normalization implies that the fraction of channels in the **O** state, out of the total N , is the quantity displayed. These realizations are compared to each others, upon increasing N , ranging from 10 to 1000 for potassium and from 12 to 1200 for sodium channels. The thick orange lines in each panel represent instead the expected value of $g_N(t)$ (see Eq. 4) under the same normalization. The generally good

agreement between fluctuating realizations and their ensemble averages, for large N (Colquhoun and Hawkes 2009a), illustrates that $E\{g_N(t)\}$ is a good representation of the collective behavior of the channel population, fully disregarding its stochastic properties.

We also remark that from the estimate of the variance of ion currents, recorded experimentally, the number N of channels underlying those currents can be also inferred (Conti and Wanke 1975).

Deterministic Description: Macroscopic Membrane Currents

The previous discussion illustrates that if the fluctuations arising from single-channel (stochastic) dynamics can be neglected (i.e., large N , in the hundreds or thousands), kinetic models and their mathematical formulation by Eq. 2 can still be employed. Equation 4 and Fig. 3 convincingly illustrate the relationship between stochastic and deterministic interpretations, which also corresponds to replacing the probability of an event in a single channel with the relative frequency of its occurrence in a population. In the last case however, the solution of Eq. 2 has a different meaning than the occupancy probabilities: it represents the fractions of state occupancies, across the channels of the population. Conceptually, this implies reinterpreting the Markov models (e.g., Figs. 1 and 2) as first-order kinetic descriptions of the fractions of channels in a given state.

Let us, for instance, consider again the two-state scheme of Fig. 1 and apply the law of mass action: the rate of a transition is proportional to the occupancy fractions of the participating states. This means that the changes in time of the fraction of channels in the state **A** and in the state **B** obey first-order kinetics. Indicating by $a(t)$ and $b(t)$ the fraction of channels in the states **A** and **B**, respectively (i.e., $a(t) + b(t) = 1$), the rate of decrease of $a(t)$ is proportional, via α , to $a(t)$ itself, while the rate of its increase is proportional, via β , to $b(t)$. Formally, this can be written as

$$\begin{aligned}\frac{d}{dt}a(t) &= -\alpha a(t) + \beta b(t) \\ \frac{d}{dt}b(t) &= \alpha a(t) - \beta b(t)\end{aligned}$$

As expected, these equations coincide with the differential equations derived for P_A and P_B : they describe in time the evolution of the ensemble average, i.e., $b(t) \approx E\{g_N(t)/\bar{g}\}$. For the same reason, the evolution of the occupancy fractions in a generic Markov model with n states is given by the solution of the homogeneous system of linear differential equations we already presented:

$$\frac{d}{dt}\mathbf{X}(t) = \mathbf{Q}\mathbf{X}(t) \quad (6)$$

where $\mathbf{X}(t)$ corresponds to $\mathbf{P}(t)$, under the relative frequency interpretation of the probabilities (i.e., as fractions). For the (deterministic) two-state model, the state vector and transition matrices take the form

$$\mathbf{X}(t) = \begin{pmatrix} a \\ b \end{pmatrix} \quad \mathbf{Q} = \begin{pmatrix} -\alpha & \beta \\ \alpha & -\beta \end{pmatrix}$$

Regardless of the conceptual differences, Eqs. 6 and 2 are formally identical and share the exact same generator matrix $\mathbf{Q}$. As done before, assuming that only one *open* state exists and referring to the fraction of channels in such a state as $o(t)$, the macroscopic membrane current is given by

$$I(t) = \bar{g}o(t)(E_x - V_m(t)), \quad o(t) = \mathbf{R}\mathbf{X}(t)$$

We conclude this section by presenting an example of a “realistic” model, employed in real application to describe deterministically macroscopic membrane currents in neuron models: a Markov model of resurgent sodium channels. This model was originally identified in a series of electrophysiological experiments (Raman and Bean 2001; Khaliq et al. 2003) and is described by the kinetic scheme of Fig. 4, with $n = 13$ states and 34 transitions.

The peculiarity of this kinetic scheme is the presence of a “blocked” state **ob**, to which ion

Markov Models of Ion Channels, Fig. 4 Kinetic scheme for a resurgent sodium channel

Markov Models of Ion Channels, Fig. 5 Time course of a subset of the state occupation fractions, in the resurgent sodium kinetic scheme of Fig. 4, upon a step change

of the membrane potential from -80 to 40 mV applied at time $t = 0$ and lasting for 5 ms. The *dashed box* is expanded in the right inset

channels quickly transition from the open state. Channels in the **ob** state need to transition again through the open state **o** in order to either inactivate (e.g., **i₆**) or close (e.g., **c₅**), which leads to the resurgent behavior typical of these ion channels. We further note that not all the rate coefficients in Fig. 4 are voltage dependent and that their large diversity gives rise to a variety of time scales, both fast and slow, in the evolution of the state occupancy fractions over time. Figure 5 shows the behavior of a subset of the state variables in response to a step of voltage from -80 to 40 mV and back. The presence of multiple time scales is clearly visible, for instance, in the dynamics of the **i₆** and **c₅** states, while the open state **o** displays the typical inactivation dynamics of the sodium channels responsible for action potential generation. The inset on the right is an expanded view around

the time of the reset of the voltage to -80 mV: the transient increase in the fraction of channels in the open state (red trace) reflects the temporary “flow” of channels occupancies out of the blocked state (blue trace in the main panel) and it gives rise to an additional tail current component.

Stochastic Simulations: Exact Methods

The generation of pseudorandom numbers (Press et al. 2007) is the most important tool for computer simulating random transitions. These routines are today available in any programming language, computing environment, or neural simulator and enable the quick simulation of a variety of deviates (e.g., uniform, Gaussian, binomial, exponential, Bernoulli). For instance, generating

a realization of a uniform deviate r in the interval $[0, 1]$ is all that is needed to generate a Bernoulli deviate (e.g., ξ , as introduced earlier). In fact, when repeatedly generating several realizations of r , the number of times its values are below a desired parameter p (e.g., 0.74) is given by p 100% (e.g., 74%). It follows that simulating the occurrence of an event with probability, e.g., $P_O(t)$, is as easy as drawing a realization of r and using it within an *if-then* construct, to test for the condition $r \leq P_O(t)$:

- The first simulation method for a Markov model of a single ion channel, implied above, consists in solving (at any time step) Eq. 2 and then refers to its solution $P_O(t) = \mathbf{R}\mathbf{P}(t)$, in order to generate Bernoulli (i.e., $g_1(t)$) or binomial (i.e., $g_N(t)$) deviates (Press et al. 2007), needed to update Eq. 3.
- When solving Eq. 2 is computationally intensive, other methods known as Monte Carlo methods can be employed (Mino et al. 2002). The method known as *brute-force* requires to keep track of the current occupied state (for each channel) in the computer memory and consists in simulating the random occurrence of transitions from one state to another of the Markov model, solving no differential equations. This must be performed for each channel and at each time step, updating the current state as the result of the occurrence of a simulated random event. These events are related to the actual transitions of the Markov model, whose probabilities are of course contained in the generator matrix $\mathbf{Q}$. In fact, a uniform deviate allows one to simulate the random occurrence of a discrete event out of many possible outcomes (e.g., $\{E_1, E_2, E_3\}$), where each has its own probability (e.g., p_1, p_2, p_3). As those probabilities sum to 1, one can graphically arrange these probabilities as (unequal) segments one next to the other, covering the range $[0,1]$ of r , as in Fig. 6. Upon drawing a realization of r , one can test by multiple *if-then-else* constructs in which of the (three, in this example) intervals the current value of r is located. The equivalent simulated random event that has just been generated is the one corresponding to such an interval, e.g., event

Markov Models of Ion Channels, Fig. 6 The random occurrence of an event out of more than two possibilities ($\{E_1, E_2, E_3\}$ in this example), such as the random transitions to one out of more possible target states in a Markov model, can be computer simulated employing a uniform pseudorandom number and testing the interval its realization falls into

E_2 when $p_1 \leq r \leq p_1 + p_2$. For example, considering a single channel described by Fig. 2 and assuming that the currently occupied state is $\mathbf{D}$, the algorithm must simulate the occurrence of a discrete event out of three possible outcomes: $\mathbf{D} \rightarrow \mathbf{E}$, $\mathbf{D} \rightarrow \mathbf{C}$, or *stay in D*. All the transition probabilities from $\mathbf{D}$ must then be listed, $p_1 = \alpha dt$, $p_2 = \beta \beta dt$, $p_3 = 1 - (\alpha + \beta \beta)dt$, and conceptually arranged in the range $[0,1]$ as in Fig. 6. Drawing a realization of r , and computing in which interval r fell, reveals which of the three events occurred and indicates whether and how the currently occupied state has to be updated. Finally, the occupancy of the open state(s) $\mathbf{O}$ is the link to the actual simulation of the ion current (Eq. 3).

- The *brute-force* method must of course be repeated for each channel and at each time step. For such a reason, it is computationally intensive for moderate to large number of channels N . Most importantly, it requires a large number of deviates to be generated. A more conservative approach is the one of an alternative method that enjoys great popularity: the Gillespie's algorithm (Gillespie 1977). This method involves *event-driven* state occupancy updates, rather than repeating the update procedure at each time step of the simulation. Let us consider a single channel: an exponential deviate T is first generated, simulating the occupancy lifetime of the current state (e.g., as in Eq. 1), with parameter λ . This parameter is the unsigned element on the diagonal of the generator matrix $\mathbf{Q}$, corresponding

to the current state. The time of the simulation is then asynchronously advanced by T , as opposed to dt . Next, the update of the (newly) occupied state is performed, by drawing again a uniform deviate r and simulating the (conditional) random occurrence of a transition (i.e., excluding by the definition of lifetime the persistence in the current state). For instance, in the example of Fig. 2 and for the currently occupied state **D**, one first obtains a realization of T_D , distributed according to\

$$f_{T_D}(T) = \lambda \exp(-\lambda T) \quad \lambda = (\alpha + 3\beta)$$

by equivalently transforming a uniform deviate r as $T = -\log \frac{r}{\lambda}$ (Papoulis and Pillail 2002; Press et al. 2007). Next, another realization of r is drawn and used to randomly simulate the occurrence of one event with two possible outcomes **D** $\rightarrow$ **E** or **D** $\rightarrow$ **C**, each occurring with (conditional) probabilities $p_1 = \alpha(\alpha + 3\beta)^{-1}dt$ and $p_2 = 3\beta(\alpha + 3\beta)^{-1}dt$. Finally, the occupancy of the open state (s) **O** is the link to the actual simulation of the ion current (Eq. 3). Gillespie's algorithm is still computationally intensive, as the time of occurrence of transitions is inversely proportional to the number of channels. Thus, when a high number of channels are considered, this algorithm takes very small time steps, which often lead to prohibitive simulation times. On the other hand, for small enough number of channels, these algorithms are very appealing, since they provide an exact simulation of the Markov stochastic kinetics.

This algorithm can be generalized and improved, for simulating a population of channels (Skaugen and Walløe 1979; Chow and White 1996): instead of tracking the state of a single channel, one can describe and simulate how the number of channels in one state must be (randomly) updated by the end of a simulated occupancy lifetime.

Stochastic Simulations: Approximate Methods

An alternative class of algorithms have also been proposed, approximating the discrete-valued

stochastic process appearing in Eq. 3 (i.e., $g_N(t)$) as a continuous *diffusion* process (Fox and Yn 1994; Fox 1997; Linaro et al. 2011; Goldwin and Shea-Brown 2011). These algorithms are collectively known as *Langevin methods*, reminiscent of the equation in statistical mechanics describing the random movement of a particle in an aqueous medium, due to collisions with the molecules of the medium (i.e., Brownian motion). Instead of keeping track of the (microscopic) random collisions with every single molecule of the medium, such an equation approximates them by an effective (macroscopic) Gaussian distributed stochastic process, modeled as an external force field in the equation of motion of the particle.

While we point the reader to the cited references for an extended discussion of this approach, we note that in the previous subsections, $g_N(t)$ has been characterized as a binomial distributed stochastic process of time. Under some circumstances (e.g., empirically as $P_{ON} > 30$), a Gaussian deviate well approximates a binomial deviate (Papoulis and Pillail 2002), so that on a first approximation, it should be apparent that $g_N(t)$ in Eq. 3 might be replaced with an ad hoc designed stochastic process with correct mean (Eq. 4) and variance (Eq. 5), among other higher-order statistical properties (Linaro et al. 2011).

This approximation, which in the limit of an infinite number of channels N must coincide with the (deterministic) solution of Eq. 6, has a lower computational load than Monte Carlo methods, and the load is independent on the number of channels, making it most appropriate for moderate to large number of channels and in multi-compartmental neuron models.

Deterministic Simulations: Numerical Methods

When the transition rates, and thus the $n \times n$ elements of **Q**, are varying in time, the solution of Eq. 6 (and Eq. 2) can only be obtained numerically, for instance, by employing Runge-Kutta method (Press et al. 2007). The update of **X**(t) in time occurs by iterating few algebraic equations at each time step of the simulation. However, if

$\mathbf{Q}$ has constant elements, at least during each small integration interval dt , a variation of the explicit Euler forward method can be employed,

$$\mathbf{X}(t + dt) \approx e^{\mathbf{Q}(t)dt} \mathbf{X}(t) \quad o(t) = \mathbf{R}\mathbf{X}(t)$$

If the transition rates are constant in time (i.e., or even piecewise constant), the exact solution can also be obtained:

$$\mathbf{x}(t) = \mathbf{X}(0)e^{\mathbf{Q}t} \quad o(t) = \mathbf{R}\mathbf{X}(t)$$

where $\mathbf{X}(0)$ is the known occupancy fraction at the initial time $t = 0$.

The exponential of a matrix appearing in both equations above can be expressed using the spectral expansion $e^{\mathbf{Q}t} = \mathbf{A}^{(1)}e^{s_1t} + \mathbf{A}^{(2)}e^{s_2t} + \dots + \mathbf{A}^{(n)}e^{s_nt}$ (Colquhoun and Hawkes 2009b). The spectral matrices $\mathbf{A}^{(i)}$ are obtained by multiplying the i th column of the matrix $\mathbf{M}$ by the i th row of the inverse matrix $\mathbf{M}^{-1}$, where $\mathbf{M}$ is the matrix that contains, column-wise, all the eigenvectors of $\mathbf{Q}$ corresponding to the eigenvalue s_i . The parameters s_i , $i = 1 \dots n$, are in fact the eigenvalues of $\mathbf{Q}$ and are the roots of a polynomial of degree n , by definition obtained as the determinant of the matrix $\mathbf{Q} - s\mathbf{I}$, where $\mathbf{I}$ is the identity matrix. For Markov models of ion channels, these roots are in general real and positive and, for simplicity, we also assume that they are all distinct. We also note that as $\mathbf{Q}$ is singular, one eigenvalue is zero and we refer to it as s_1 .

From these considerations, $o(t)$ can be expressed as a simple weighted sum of exponential terms:

$$o(t) = o_\infty + h_2e^{s_2t} + h_3e^{s_3t} + h_4e^{s_4t} + \dots + h_ne^{s_nt}$$

In the previous expression, we have indicated by $O_\infty = \mathbf{R}\mathbf{X}_\infty$ the element corresponding to the open state $\mathbf{O}$, within the steady-state state vector $\mathbf{X}_\infty$ of Eq. 6. This can be obtained by linear algebraic methods as a solution of the equation $\mathbf{Q}\mathbf{X}_\infty = 0$ or more efficiently as

$$o_\infty = \mathbf{u}(\mathbf{S}^T\mathbf{S})^{-1}\mathbf{R}^T$$

where the matrix $\mathbf{S}$ and its transpose $\mathbf{S}^T$ have been obtained from $\mathbf{Q}$ by addition of an extra (rightmost) column composed of n identical unitary elements, while $\mathbf{u}$ is a (row) vector of n identical unitary elements (Colquhoun and Hawkes 2009b).

Finally, the coefficients $h_2, h_3, \dots, h_n$ are found as the (k th) row in the matrix $\mathbf{W}$ that corresponds to the open state $\mathbf{O}$ within $\mathbf{X}$ (i.e., $\mathbf{O}$ is the k th element of $\mathbf{X}$). The elements of $\mathbf{W}$ are computed as

$$w_{ij} = \sum_{r=1}^n \mathbf{x}_r(0)\mathbf{a}_{rj}^{(i)}$$

where $\mathbf{x}_r(0)$ is the r th element of $\mathbf{X}(0)$ and $\mathbf{a}_{rj}^{(i)}$ is the generic element of the spectral matrix $\mathbf{A}^{(i)}$.

Independent, Multiple Subunits' Markov Models

We have introduced and described so far a Markov model by means of a single-weighted directed graph. In some cases however, heuristic, experimental, or biophysical considerations may suggest symmetries and constraints on the geometrical arrangement and on the values of the rate coefficients (e.g., compare the scheme of Fig. 2 with the one of Fig. 4). Under these circumstances, a model with several states can be equivalently formulated as a set of Markov models, where each of them has an active and an inactive state (as in Fig. 1). Individual subsystems may not necessarily share identical transition rates and, as a whole, the entire system is said to be in the open state when all its parts are simultaneously activated.

The ionic permeability through a single channel is often attributed to the activation of multiple, independent, protein subunits, which together form the ionic pore through the membrane (Hille 2001). In these cases, following the approach originally proposed by Hodgkin and Huxley (1952), the dynamics of activation of each subunit may be

described as a 2-state Markov model, and the resulting membrane permeability is referred to the activations of all subunits at the same time. The single-channel conductance is then readily obtained as a new Bernoulli random variable η , $g_1(t) = \gamma \eta$ obtained multiplying together the elementary independent Bernoulli variables, each associated with a distinct subunit, e.g., $\eta = \xi^{(1)}(t)\xi^{(2)}(t)\xi^{(3)}(t)\xi^{(4)}(t)$, where each $\xi^{(k)}$ takes the value 1 with probability $P_{\mathbf{B}}(t)$ of the corresponding subunit graph. In the previous example, four independent subunits have been considered, and the channel is in the open state when all four are in an activate state (i.e., all in **B**). By describing each subunit by the same kinetic model of Fig. 1 (i.e., same α and β for all four subunits), it is easy to prove that this new description and the one of Fig. 2 are statistically equivalent.

It is possible to rewrite Eq. 3 for the stochastic description of single-channel currents as

$$I_1(t) = \gamma \eta (E_x - V_m(t))$$

$$I(t) = \gamma (\eta_1 + \eta_2 + \dots + \eta_k + \dots + \eta_N) (E_x - V_m(t))$$

and for the deterministic description of macroscopic membrane currents as

$$I(t) = \bar{g} \quad b(t)^4 (E_x - V_m(t))$$

The experimental identification and simulation of these channels is simpler than the full models discussed so far. This is apparent by inspecting the way the analytical expressions of the transient and steady-state solutions of Eq. 2 (and Eq. 6) reduce for multiple subunits, under the hypotheses of time invariance of the rate coefficients already mentioned earlier:

$$P_{A\infty} = a_{\infty} = \frac{\beta}{\alpha + \beta} \quad P_{B\infty} = b_{\infty} = \frac{\alpha}{\alpha + \beta}$$

and

$$P_A(t) = (P_A(0) - P_{A\infty})e^{-(\alpha+\beta)t} + P_{A\infty}$$

$$P_B(t) = (P_B(0) - P_{B\infty})e^{-(\alpha+\beta)t} + P_{B\infty}$$

$$a(t) = (a(0) - a_{\infty})e^{-(\alpha+\beta)t} + a_{\infty}$$

$$b(t) = (b(0) - b_{\infty})e^{-(\alpha+\beta)t} + b_{\infty}$$

Limitations

One of the main assumptions underlying the application of Markov models is the independence of the ion channels in a population. It has been proposed that this assumption may not be always accurate (Undrovinas et al. 1992; Marx et al. 2001) and that coupled gating, i.e., *cooperativity* in transition probabilities, should be instead considered. This was more recently suggested to be hypothesized, at least in specific compartments of neuronal morphologies, such as the axon initial segment, to explain experimental observations. As a consequence, a single-compartmental model has been proposed (Naundorf et al. 2006) that incorporates cooperativity among (groups of) sodium ion channels, where the rate coefficients of each channel depend on the occupancy state of neighboring channels. It was then shown that cooperativity explains some dynamical feature of action potential initiation in cortical neurons, in particular the steep slope of the membrane potential observed both *in vitro* and *in vivo* at the onset of the action potential.

However, it is important to note that analogous results have been obtained by employing independent sodium ion channels in a multi-compartmental neuron model (Yu et al. 2008).

Another fundamental assumption is that there exists a discrete set of stable configurations (i.e., states) in which an ion channel can reside. An alternative description has been introduced (Liebovitch and Tóth 1990), in which fractals are used to analyze single-channel data, leading to the introduction of a continuum of states, instead of the discrete set commonly used. This makes the transition probabilities depend on time, making the analysis, identification, and simulation more elaborate.

It is not however clear whether either of these alternative formulations realistically captures the biophysics of membrane permeability (Colquhoun and Hawkes 2009a).

Masking and Masking Release

Andrew J. Oxenham

Department of Psychology, University of
Minnesota, Minneapolis, MN, USA

Definition

Masking has a technical definition of “the process ... and the amount by which the threshold of hearing for one sound is raised by the presence of another (masking) sound” (ANSI 2013). Masking release does not have such an established definition but refers to both the process and the amount by which masking is decreased by some manipulation of the masking or target sound.

Detailed Description

Masking is the process by which the presence of one sound makes another sound more difficult to hear. We all encounter masking in our everyday lives, when we fail to hear the phone ring while we are having a shower or when we struggle to follow a conversation in a noisy restaurant. In general, a more intense sound will mask a less intense sound, but masking also depends on the time and frequency relations between the sounds. In fact, much of the masking we encounter in everyday life can be explained in terms of processes that occur in the ear itself.

Origins of Masking

When sound enters the ear, it sets in motion a complex chain of events that results in the movement of the basilar membrane within the cochlea. The cochlea acts something like an acoustic prism, splitting sound up into its constituent frequency components. Each frequency within a sound sets up a traveling wave along the basilar membrane, which peaks at a point along the basilar membrane that is related to its frequency: high frequencies reach a peak closer to the base of

the cochlea, whereas low frequencies travel further along the basilar membrane, reaching a peak nearer to the apex of the cochlea. Von Békésy was awarded the 1960 Nobel Prize in Physiology and Medicine for his discovery of the traveling wave within the cochleae of human cadavers (von Békésy 1960).

Masking is often based on the extent to which the pattern of motion on the basilar membrane produced by the masking sound (the masker) interferes with the pattern of motion produced by the target sound (the maskee). Because of the way that filtering in the cochlea functions, low frequencies are more likely to mask high frequencies than vice versa, particularly at high sound intensities. This asymmetric aspect of masking at high intensities is known as the “upward spread of masking” (Egan and Hake 1950). Recent studies have found that behavioral and physiological measures produce very similar estimates of filter sharpness and shape (Shera et al. 2002; Sumner et al. 2018), strengthening the argument that many aspects of perceptual masking can be explained in terms of cochlear processing. The loss of sharp cochlear tuning that often accompanies cochlear damage leads to broader filtering and more masking – a physiological phenomenon that is likely to contribute to the difficulties experienced by people with hearing loss in noisy environments (Moore 2007).

Nonsimultaneous Masking

Most masking occurs when the masker and target overlap in time. This situation is known as simultaneous masking. In contrast to the visual system, the auditory system is relatively fast, so, unless the masker is loud enough to cause temporary or permanent hearing loss, the effects of a masker do not extend far beyond the end of the masker in time. However, if a very brief target occurs within 100–200 ms of the end of a masker, some “forward masking” will occur. “Backward masking” occurs when the audibility of a target is reduced by a masker that follows the target in time. However, the effect is generally small, extends for only a few milliseconds, and can

become almost negligible after extended practice (Oxenham and Moore 1995). It remains unclear where in the auditory system nonsimultaneous masking occurs. Cortical processes are suggested by the long learning period associated with backward masking, and even forward masking seems likely to be governed by processes higher than the auditory nerve (Relkin and Turner 1988; Oxenham 2001).

Informational Masking

Masking based on interactions within the cochlea is often termed “energetic masking.” There are other forms of simultaneous masking that can occur even when interactions within the cochlea are unlikely. These other types of masking come in different forms but have often been categorized together under the term “informational masking” (Watson 1987; Durlach et al. 2003). Relatively little is known about the causes of informational masking, although most forms can be ascribed to a perceptual “fusion” of the masker and target sounds and/or “confusion” of the target with elements of the masker. Relatively little is also known about the neural loci of informational masking, except that at least some forms seem to originate in the auditory cortex and not before (Gutschalk et al. 2008).

Speech Masking

One of the most important examples of masking is when speech is rendered difficult to understand by competing sounds in noisy environments. In a background of quasi-stationary noise, such as air-conditioning or heavy traffic, masking seems to be dominated by energetic masking, and speech intelligibility can often be well predicted by considering just the power spectrum of the speech and the noise (ANSI 1997). In more complicated, fluctuating maskers, such as someone else talking, masking appears to be a combination of energetic and informational masking.

Practical Applications

Quantitative models of auditory masking date back at least to the power spectrum model of Fletcher (1940) and more recently incorporate nonlinear aspects associated with

cochlear mechanics and auditory-nerve responses (Lopez-Poveda and Meddis 2001; Zilany and Bruce 2006). Even relatively simple models of masking, based on the spread of excitation within the cochlea, can produce reasonably accurate predictions of how audible a given target will be in the presence of a given masker; thus, our knowledge of auditory masking has practical implications for the design of acoustic signals and auditory warnings, such as ambulance sirens (Patterson and Mayfield 1990).

Although masking has disadvantages, such as making speech or warning signals more difficult to understand in noisy environments, it can also be used to advantage in some situations. For instance, low bit-rate digital coding of speech and music, using formats such as MP3, relies on auditory masking (Brandenburg 1999). Reducing the resolution of the digital code to save space results in a noisier recording, but the coding algorithm ensures that the additional noise is masked by the music or speech itself, so that there is little or no perceptual degradation of the signal.

Masking Release

The term masking release refers to a reduction in masking produced by a change in either the masker or the target. The most commonly studied forms of masking release involve changes to the spatial relations between the masker and target. For instance, if the maskers and target are both located in front of the listener and the maskers are then moved to the left and right of the target, some masking release may occur, because the binaural system can now take advantage of differences between the ears to extract more information about the target (Gallun et al. 2005). Differences in other features, such as pitch or vocal tract length, between the target and maskers can also lead to masking release (Darwin et al. 2003). Another form of masking release involves introducing amplitude modulation to the masker. The amplitude modulation introduces momentary improvements in the target-to-masker ratio, which can lead to improved audibility of both speech and non-speech targets (Gregan et al. 2013). Hearing loss often leads to reduced masking release (Marrone et al. 2008) for reasons

that may include reduced audibility, poorer peripheral encoding of suprathreshold sounds, and impaired binaural processing.

Master Stability Function for Globally Synchronized Systems

Louis M. Pecora and Thomas L. Carroll
U.S. Naval Research Laboratory, Washington,
DC, USA

Definition

One of the most common structures of dynamical systems in a network is the basic situation of

having all the network nodes being identical oscillators or other dynamical systems and the edges being different couplings between the nodes and oscillators. A basic question in this case is whether all the oscillators can synchronize with each other creating an emergent, extremely coherent state and, if this motion is possible, under what circumstances is it stable. We show here that the case of identical synchronization (all oscillators are executing identical dynamical motions at the same time) permits the solution of the stability equations in a very simple form which decomposes the perturbation dynamics into synchronized and unsynchronized perturbations, greatly reduces the computations, and allows generalizations about the synchronization conditions and system parameters to be made.

Detailed Description

The General Dynamical Equations

Synchronized behavior is a collective phenomenon and its occurrence indicates a cooperative or constrained action. It is a pattern of dynamics that greatly simplifies motion in what could be a complex network of systems. Such behavior might model many systems in physics, chemistry, or biology. A few examples are networks of magnetic spins, chaotic chemical reactions, flocking or schooling of animals, and firing of neurons. Given such applications, it would be useful if we could say some general things about such dynamics and, especially, find ways to simplify the analysis of many networks of oscillators. To do this, we need to set up the structure of such a system and identify the right questions to ask.

The mathematical questions are the following. Given a set of identical or nearly identical oscillators in a network, under what conditions can they sustain synchronized behavior? Here by synchronized we mean that they are all doing the same dynamics (or nearly so) at the same time. If the answer is yes, then an additional important question is, for what parameter values (e.g., coupling strength) is the synchronized state stable?

The first question will put constraints on the equations of motion. Here we use ordinary differential equations (ODE) although most of what is presented here generalizes to other situations, e.g., iterated maps. We will start with simple models and generalize.

Since we want the oscillators in the network to be identical, we can start with a network where each node is an oscillator whose isolated dynamics is given by a differential equation

$$\frac{dx}{dt} = \mathbf{F}(\mathbf{x}). \quad (1)$$

Here $\mathbf{x}$ and $\mathbf{F}$ are n -dimensional vectors. The simplest way to connect them in a network is to label each node's vector by its number in a subscript on the vector and write the general ODE for each node as

$$\frac{d\mathbf{x}_i}{dt} = \mathbf{F}(\mathbf{x}_i) + \sigma \sum_{j=1}^N C_{ij} \mathbf{x}_j, \quad (2)$$

where there are N nodes in the network and σ is the overall coupling strength. If any two nodes are not coupled, we set the coupling matrix $C_{ij} = 0$. Note that each node has the same vector field. However, we still have to check that synchronized dynamics is possible. If we put the network in a synchronized state, we have $\mathbf{x}_i = \mathbf{s}$ for all nodes, where $\mathbf{s}$ is any n -dimensional vector. The constraint $\mathbf{x}_i = \mathbf{s}$ defines a subspace that is a submanifold of the whole space where all the components of the dynamical node vectors are equal. This is often called the **synchronization manifold**, and it is the n -dimensional analog of the 45° diagonal in two dimensions where “ $x = y$.” It is easy to see that if we do this in Eq. 2, the motion will not stay in a synchronous state in general, i.e., the system will generally evolve to a state where the $\mathbf{x}_i$ are not all equal. If we substitute $\mathbf{x}_i = \mathbf{s}$ into Eq. 2, we get

$$\begin{aligned} \frac{ds}{dt} &= \mathbf{F}(\mathbf{s}) + \sigma \sum_{j=1}^N C_{ij} \mathbf{s} \\ &= \mathbf{F}(\mathbf{x}_i) + \sigma \left(\sum_{j=1}^N C_{ij} \right) \mathbf{s} \text{ for node } i. \end{aligned} \quad (3)$$

The only way all nodes have the same behavior is to have the sum, $\sum_{j=1}^N C_{ij}$, be the same for all i . Hence, our first restriction to get complete, identical synchronization is that the row sums of the coupling matrix must be the same for all rows. Very often, the row sum is taken to be zero. This means the motion for all coupling strengths σ is the same as given by Eq. 1; otherwise, the synchronized motion changes as coupling-strength changes. When the row sum is zero, the coupling is often described as being in a **Laplacian** form which is a term from graph theory, the mathematics of networks and their structure. A constant row sum means that if the motion is started in a synchronized state, it remains in a synchronized state. Mathematically, it is said that the synchronized state is **flow invariant**. This is a requirement to have synchronized motion.

We can rewrite the equations of motion so that the coupling has zero row sum by defining a new vector field $F'_i(x_i) = F(x_i) + \left(\sigma \sum_{j=1}^N C_{ij} \right) x_i$ so that the equations of motion become

$$\frac{dx_i}{dt} = F'_i(x_i) + \sigma \sum \left[C_{ik} - \left(\sum_{j=1}^N C_{ij} \right) \delta_{ik} \right] x_j, \quad (4)$$

where the new coupling matrix has zero row sum. We must remember that this case has different dynamics than the Laplacian form. In the Laplacian case, the synchronized motion is the same for all coupling strengths σ , but in Eq. 4 the synchronized dynamics depends on σ because of the extra term in F'_i .

We can generalize the above situation by using an output function $\mathbf{H}$ from each node's oscillators instead of just the dynamical variable. $\mathbf{H}$ is the same for all oscillators. The equations of motion would then look like

$$\frac{dx_i}{dt} = F(x_i) + \sigma \sum_{j=1}^N C_{ij} H(x_j). \quad (5)$$

It is easy to show that the requirement for the existence of a synchronized state is again that all row sums of the coupling matrix C_{ij} are equal. Equation 5 is much more general than Eq. 3. It includes the case of coupling through only a few components of each node rather than all of them and various nonlinear functions of each node's components.

Finally, we consider a very general case which is useful to think about since it forces us to think more deeply about the phenomenon of synchronization. Let the vector $\mathbf{x}$ be the collection of all the N node dynamical vectors $\mathbf{x}_i$, that is, we can write $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N)^T$. From here on, we assume all the vectors are actually column vectors, but we will suppress the transpose T in the notation. Now we write the network's equation of motion as

$$\frac{d\mathbf{x}}{dt} = \mathbf{G}(\mathbf{x}), \quad (6)$$

where $\mathbf{G}$ is a vector of functions $\mathbf{G} = (\mathbf{G}_1, \mathbf{G}_2, \dots, \mathbf{G}_N)$ so that the equation of motion for each node is $\frac{dx_i}{dt} = G_i(\mathbf{x})$. That is, each node has dynamics that is tailored for it. For example, using the above, we would have $G_i(\mathbf{x}) = F(x_i) + \sigma \sum_{j=1}^N C_{ij} x_j$,

although we are now allowing much more general functional forms. As before, we need to constrain the dynamic functions to ensure total synchronization of the nodes. This means we want the synchronized state to be flow invariant, so that if we start in a synchronized state $\mathbf{S} = (\mathbf{s}, \mathbf{s}, \dots, \mathbf{s})$, we stay in a synchronized state, i.e., we stay on the synchronization manifold. This requires

$$G_i(\mathbf{S}) = G_j(\mathbf{S}) \forall i, j. \quad (7)$$

Note: this equality only need hold on the synchronization manifold. We can't say much beyond this, but in the next section, we will make some simplifying assumptions that will enable the analysis to continue for the most general case.

Stability of the Synchronized State

If our system obeys the synchronization constraints of the previous section, it will support

synchronized motion. This leads to an important question: will the synchronized motion be stable? In most experiments and real systems, if synchronized motion is not stable, we will never see it. Any small perturbation will grow and the dynamics will move away from synchronization to some other dynamical behavior. Here we will examine the criteria for linear stability, that is, that small perturbations to the dynamical variables $\{\mathbf{x}_i\}$ will generally die out and the system will return to its synchronized state where $\mathbf{x}_i = \mathbf{s} \forall i$. We will be able to derive some very general results using linear stability, but the reader should be aware that there are other criteria for synchronization such as Lyapunov functions (Guckenheimer and Holmes 1983). These are stronger conditions for synchronization, but much harder to prove and generalize.

Suppose our system is synchronized and we perturb it so that each node is, in general, slightly “away” from the synchronized motion. As before, let $\mathbf{s}(t)$ represent the synchronized motion. We want to consider what happens when we replace each node’s dynamics with dynamics slightly different from the synchronized state. Let ξ_i be a small perturbation of the i th node so that after the perturbation, $\mathbf{x}_i = \mathbf{s} + \xi_i$. We can now derive an equation of motion for the small perturbations which will tell us if they will grow or shrink, that is, if the synchronized state is unstable or stable, respectively.

We’ll start with the simplest form of dynamics, Eq. 2. The perturbed equations are

$$\frac{d(\mathbf{s} + \xi_i)}{dt} = \mathbf{F}(\mathbf{s} + \xi_i) + \sigma \sum_{j=1}^N C_{ij}(\mathbf{s} + \xi_j)$$

If we subtract the equations of motion from the above, we get

$$\frac{d\xi_i}{dt} = \mathbf{F}(\mathbf{s} + \xi_i) - \mathbf{F}(\mathbf{s}) + \sigma \sum_{j=1}^N C_{ij}\xi_j$$

Now we use Taylor’s theorem and expand $\mathbf{F}(\mathbf{s} + \xi_i)$ to first order (since ξ_i is small) to get

$$\begin{aligned} \mathbf{F}(\mathbf{s} + \xi_i) &\approx \mathbf{F}(\mathbf{s}) + \left. \frac{\partial \mathbf{F}}{\partial \mathbf{x}} \right|_{\mathbf{x}=\mathbf{s}} \cdot \xi_i \\ &\equiv \mathbf{F}(\mathbf{s}) + D\mathbf{F}(\mathbf{s}) \cdot \xi_i \end{aligned}$$

where we have defined the Jacobian $D\mathbf{F}$ evaluated on the synchronized state. $D\mathbf{F}$ is a matrix which multiplies the perturbation ξ_i . Combining the last two equations, we get the equation of motion for the perturbations also called the **variational equations** of the dynamics

$$\begin{aligned} \frac{d\xi_i}{dt} &= D\mathbf{F}(\mathbf{s}) \cdot \xi_i + \sigma \sum_{j=1}^N C_{ij}\xi_j \\ &= \sum_{j=1}^N [\delta_{ij} D\mathbf{F}(\mathbf{s}) + \sigma C_{ij} \mathbf{1}_n] \cdot \xi_j \end{aligned} \quad (8)$$

where δ_{ij} is the Kronecker delta and $\mathbf{1}_n$ is the $n \times n$ **identity matrix**. Equation 8 is the equation of motion for the evolution of the perturbations ξ_i . Note that it is time dependent (through $\mathbf{s}(t)$) and linear.

We can write Eq. 8 more compactly using direct or tensor product notation which is very handy when manipulating linear matrix equations of this form. Given two matrices, $\mathbf{A}$ being $m_1 \times n_1$ in dimension and $\mathbf{B}$ being $m_2 \times n_2$ in dimension, we define the $(m_1 + m_2) \times (n_1 + n_2)$ matrix $\mathbf{C}$ by the direct product

$$\begin{aligned} \mathbf{C} &= \begin{pmatrix} A_{11}\mathbf{B} & A_{11}\mathbf{B} & \cdots & A_{11}\mathbf{B} \\ A_{21}\mathbf{B} & A_{22}\mathbf{B} & \cdots & A_{2n_1}\mathbf{B} \\ \vdots & \vdots & \vdots & \vdots \\ A_{m_1 1}\mathbf{B} & A_{m_1 1}\mathbf{B} & \cdots & A_{m_1 n_1}\mathbf{B} \end{pmatrix} \\ &\equiv \mathbf{A} \otimes \mathbf{B}, \end{aligned}$$

where, for example, the upper left-hand block $A_{11}\mathbf{B}$ is $m_2 \times n_2$ and consists of A_{11} times the matrix $\mathbf{B}$. The advantage of this notation is that one can operate on the first and second factors of the direct product separately, namely, $\mathbf{A} \otimes \mathbf{B} \cdot \mathbf{D} \otimes \mathbf{E} = (\mathbf{A} \cdot \mathbf{D}) \otimes (\mathbf{B} \cdot \mathbf{E})$, assuming the dimensions of the matrices are properly matched. Using this notation, we write

$$\frac{d\tilde{\xi}}{dt} = \left[\mathbf{1}_N \otimes DF(s) + \sigma C \otimes \mathbf{1}_n \right] \cdot \tilde{\xi}, \quad (9)$$

where $\tilde{\xi} = (\xi_1, \xi_2, \dots, \xi_N)$ and $\mathbf{1}_N$ is the $N \times N$ identity matrix.

Solutions of Eq. 9 yield perturbations which will (very roughly speaking) grow or shrink exponentially. Thus (abusing the notation), $\xi_i e^{\mu_i t}$. The exponents μ_i tell us if the perturbation grows ($\mu_i > 0$) or shrinks ($\mu_i < 0$), the former indicating a direction that is unstable and the latter a stable direction. In order for the synchronized state to be stable, all exponents must be negative. There are standard ways to calculate the exponents. When the behavior is periodic, one calculates **Floquet multipliers** or **exponents** (Guckenheimer and Holmes 1983), and when the behavior is chaotic, one calculates **Lyapunov exponents** (Guckenheimer and Holmes 1983).

However, there are two problems with Eq. 9: one is structural and the other problematic in efficiency. The structural problem arises because we don't want to consider all perturbations. One way to cover all possible perturbations is to take all components of perturbations and run them through the variational equation to get all stability exponents. This means we replace the single column vector of perturbations $\tilde{\xi}$ with a matrix of perturbations in all components

$$\begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{pmatrix} \delta,$$

where δ is a small n -dimensional vector. We can evolve the above identity matrix and calculate all exponents, in principle. The problem comes in that we have not separated the synchronous perturbations from the nonsynchronous perturbations. The synchronous perturbations simply add the same perturbation to all nodes keeping them synchronized. This tells us the exponents of the synchronous dynamics which will tell us nothing about whether the nonsynchronous perturbations die out or grow. The latter tells us if the

synchronous state is stable. We have to find a way to get the synchronous perturbations separated from the nonsynchronous (transverse) perturbations.

The second problem is efficiency of the calculations. We only need the largest exponents (Floquet or Lyapunov) to tell us about the stability of the transverse perturbations. But we are calculating nN exponents. If we have 100 nodes each with a three-dimensional oscillator, we have $nN = 300$ dynamical perturbation variables.

We can solve both the structural and efficiency problem with one transformation of the variational equations. If we look at Eq. 9 and concentrate on the first matrix in each term, we see that the first term is diagonal ($\mathbf{1}_N$), but the second is not. However, we can diagonalize the σC factor, and this will not affect the first term since $\mathbf{1}_N$ commutes with the diagonalizing transformation matrices. This leaves us with variational equations which are diagonal in the node coordinates and are now uncoupled and individually look like

$$\frac{d\zeta_k}{dt} = [DF(s) + \sigma \lambda_k \mathbf{1}_n] \cdot \zeta_k \quad (10)$$

where λ_k is an eigenvalue associated with the eigenvector direction of ζ_k of the network given by C .

We can now make an important observation. All the eigenvalue perturbation equations are of the same form. Only the eigenvalue is different in each. If we take the general form of the variational equation (Eq. 10) to be

$$\frac{d\zeta}{dt} = [DF(s) + \sigma z \mathbf{1}_n] \cdot \zeta, \quad (11)$$

where z is a complex number (in general, the eigenvalues of C are complex since C is not necessarily symmetric). Now if we calculate the maximum exponent of Eq. 11 on a fine grid over the complex plane sufficiently large to encompass all eigenvalue $\times$ coupling strength products of Eq. 10, then for any network of this particular oscillator with the coupling we chose above, we can quickly find the stability of all the possible

eigen-directions by looking up the value of the product $\sigma\lambda_k$ on the grid and reading its stability exponent. If that exponent is negative, the eigenmode is stable, and if positive, the eigenmode is unstable. It is easy to show that the eigenvector associated with the synchronization manifold is given by $\zeta_0 = (1, 1, \dots, 1)$. Hence, we look at the exponents associated with all other eigenvalues and those are the transverse (nonsynchronous) perturbations.

We have reduced the number of computations by this eigenvalue transformation, decoupled the transverse and synchronous perturbations, and provided once and for all a function on a grid in the complex plane which gives the stability of the transverse modes for any network $\mathbf{C}$ that we choose for this oscillator. This function is called the **master stability function**. The master stability function (MSF) is a function on $\mathbb{C} \rightarrow \mathbb{R}$. If the network is symmetric, then the eigenvalues are real and the MSF is a function on the real line, $\mathbb{R} \rightarrow \mathbb{R}$. Once the MSF is known for an oscillator and coupling type, then the stability of the synchronous state for any network of that oscillator is just an eigenvalue calculation for the coupling matrix $\mathbf{C}$.

Figure 1 shows a schematic of one type of an MSF ($\mu_{\max}$) as a function of $z = \alpha + i\beta$. Inside the red boundary is the stable zone. If all coupling $\times$

Master Stability Function for Globally Synchronized Systems, Fig. 1 The MSF $\mu_{\max}(\alpha, \beta)$ for a fictional oscillator shown just to acquaint the reader with the concept

eigenvalue products for a network of identical oscillators fall inside the red boundary, then the synchronization state is stable. If even one product falls outside the stable zone, then that eigenmode is unstable and the synchronization state is unstable. In fact the first instability the synchronization state will display as it goes unstable will the spatial pattern of the eigenvector associated with the unstable mode. This is shown in more detail in Pecora (1998).

Using the same formulation as above, it is easy to show that the perturbation equation for the MSF for the more general coupling case (Eq. 5) is

$$\frac{d\zeta}{dt} = [DF(s) + \sigma z DH(s)] \cdot \zeta, \quad (12)$$

where we now have the Jacobian of the coupling or output function $\mathbf{H}$. Now the MSF will depend on the coupling function, too. But, again, for the same vector field and coupling function, we can calculate the stability of the synchronized state once and then easily determine the stability of any network with those oscillators and coupling.

Finally, we can produce an MSF for the more general case Eq. 6 if we make some simplifying assumptions about the Jacobians of the general vector field for the whole system $\mathbf{G}(\mathbf{x})$. Starting with the general variational equation, we separate out the diagonal terms in the Jacobian ($D_i \mathbf{G}_j = j$) from the off-diagonal terms ($D_i \mathbf{G}_j \neq j$),

$$\frac{d\zeta_i}{dt} = \left[D_i \mathbf{G}_i(s) + \sum_{i \neq j} D_i \mathbf{G}_j(s) \right] \cdot \zeta_i$$

Since we are using identical oscillators, the diagonal terms are all the same function form, and we set them equal to $D_i \mathbf{G}_i(s) = DF(s)$. And since we expect the coupling functional forms to be the same for all nodes in the network, we set $D_i \mathbf{G}_j$ proportional to the same function of s , namely, $D_i \mathbf{G}_j(s) = C_{ij} \mathbf{H}(s)$, and we note these simplifications only need hold on the synchronization manifold. Hence, even a very general case may possibly have a variational form that permits the calculation of an MSF from an ODE form like Eq. 12.

Calculated Examples of MSFs

Here we show contour plots of the MSF for a Rössler-like oscillator for two different coupling functions $\mathbf{H}$. If we let x_i^j be the j th component of the i th node's dynamical variable, the nodes are assumed to have oscillators which obey the equations

$$\begin{aligned}\frac{dx_i^1}{dt} &= -k(ax + by + cz) \\ \frac{dx_i^2}{dt} &= -k(x + fy) \\ \frac{dx_i^3}{dt} &= -k(-g(x_i^1) + x_i^3) \\ \text{with } g(x_i^1) &= \begin{cases} 0, & \text{if } x_i^1 \leq 3 \\ h, & \text{if } x_i^1 > 3 \end{cases}\end{aligned}\quad (13)$$

where $a = 0.05$, $b = 0.5$, $c = 1.0$, $f = 0.133$, and $h = 15$. The constant k is simply a time-scaling factor, which for our system is 104 s^{-1} . An isolated node produces an attractor that is similar to the original Rössler system as shown in Fig. 2. The Jacobian of Eq. 13 is

$$DF(x_i) = \begin{pmatrix} -kax_i^1 & -kbx_i^2 & -kcx_i^3 \\ -kx_i^1 & -fx_i^1 & 0 \\ -k\frac{dg}{dx}|_{x_i^1} & 0 & -kx_i^3 \end{pmatrix}$$

Master Stability Function for Globally Synchronized Systems, Fig. 2 The attractor of the Rössler-like oscillator

We choose our first coupling function to be

$$\mathbf{H}(x_i) = \begin{pmatrix} x_i^1 \\ 0 \\ 0 \end{pmatrix} = D\mathbf{H}(x_i).$$

In other words, we are coupling all the oscillators in our network through only the first component. Now we can use Eq. 12 with the above substitutions to generate the MSF for this oscillator in a network with the given coupling above. This is shown in Fig. 3.

The MSF for the x_i^1 -coupled case has a finite, single minimum stability region. Networks of this oscillator will only synchronize if the coupling-strength-eigenvalue products all fall into the stability island. For some networks, it is not possible to get all products in the stable region, and it is possible to cause desynchronization if the

Master Stability Function for Globally Synchronized Systems, Fig. 3 The MSF for the x_i^1 -coupled Rössler-like system in the complex plane, $z = \alpha + i\beta$. Note that when the real part of the coupling goes near zero, the synchronized state is not stable. This is the result of the fact that the attractor for each node is chaotic, and without dissipative coupling, the nodes will naturally diverge from a synchronized state when slightly perturbed

coupling becomes too large. We explain more about this next when we examine the symmetric coupling case.

In the symmetric coupling case, the eigenvalues of the coupling matrix are real so that we have an MSF that is a mapping $\mathbb{R} \rightarrow \mathbb{R}$. Figure 4 shows this for the Rössler-like oscillator with coupling through the first component as above. We see that there is an unstable region (the MSF is > 0) from a coupling of $\alpha = 0$ to α_1 , a stable region (the MSF is < 0) from α_1 to α_2 , and an unstable region from α_2 to ∞ . Having a limited coupling region for stability (α_1, α_2) leads to some interesting phenomena. Suppose we have N oscillators coupled in a ring through nearest neighbor coupling only (see inset, Fig. 4), then the eigenvalues of the coupling matrix are

$$\lambda_k = 4\sigma \sin^2\left(\frac{\pi k}{N}\right). \quad (14)$$

The $k = 0$ eigenvalue belongs to the synchronization manifold so we do not use it for stability calculations of the transverse perturbations. The smallest eigenvalue is $\lambda_1 = 4\sigma \sin^2(\pi/N)$ which becomes very small as N increases, but we can always keep $\lambda_1 > \alpha_1$ by

Master Stability Function for Globally Synchronized Systems, Fig. 4 The MSF for a symmetrically coupling array of Rössler-like oscillators. The stability range of coupling $\times$ eigenvalues is limited to a finite region

increasing the coupling σ . However, the largest eigenvalue is $\lambda_{N/2} = 4\sigma$ (assuming for now that N is even). Thus, increasing the coupling will eventually cause the largest eigenvalue to become greater than α_2 . This has two consequences.

One is that there will be rings of oscillators which have limited stability ranges of coupling $\times$ eigenvalue for which adding more oscillators to the ring will cause the synchronized state to become unstable and be impossible to stabilize by varying the overall coupling, i.e., there will be a “size effect,” beyond which rings (or other suitable networks) cannot be enlarged or stability will be lost. Another interesting effect is that increasing the coupling when there is an upper bound on the stability region can cause the synchronized state to destabilize. This is somewhat counterintuitive and causes the highest mode to go unstable rather than the lowest (just above $\alpha = 0$) to go unstable. For a ring, the highest mode is the one with the highest spatial frequency. Such instabilities are often called short-wavelength bifurcations (Heagy et al. 1995).

We can compare the limited stability range above with the infinite stability range of the same oscillators, but with different coupling function **H**. Here we let the coupling be through the second component of the oscillators

$$H(x_i) = \begin{pmatrix} 0 \\ x_i^2 \\ 0 \end{pmatrix} = DH(x_i).$$

Figure 5 shows the MSF for this case. There remains a “gap” of instability near $\alpha = 0$, but then there is an infinite stability region beyond that. In this system there are no side effects or short-wavelength bifurcations.

Experimental Determination of MSFs

So far we have focused on the calculation of MSFs, but an important question is, is there any experimental way to access the shape or values of the MSFs? The answer is “yes,” and here we show one way a simple experimental setup can determine the shape of the stable region of the MSF.

Master Stability Function for Globally Synchronized Systems, Fig. 5 The MSF for Rössler-like oscillators using coupling through the second component

This depends on the ability to experimentally control the coupling between oscillators in a simple network. This is certainly possible in electronic circuits and may be possible in other systems (e.g., some using chemical oscillators or neurons where certain chemicals might enhance or diminish coupling strength).

To see how to do this, let's take the simple three-oscillator system shown in Fig. 6.

The coupling matrix (C) is given by

$$C = \begin{pmatrix} -2\frac{\alpha}{3} & \frac{\alpha}{3} + \frac{\beta}{3} & \frac{\alpha}{3} - \frac{\beta}{3} \\ \frac{\alpha}{3} - \frac{\beta}{3} & -2\frac{\alpha}{3} & \frac{\alpha}{3} + \frac{\beta}{3} \\ \frac{\alpha}{3} + \frac{\beta}{3} & \frac{\alpha}{3} - \frac{\beta}{3} & -2\frac{\alpha}{3} \end{pmatrix}. \quad (15)$$

This may look unnecessarily complicated, but viewing the eigenvalues of C associated with the transverse perturbation directions, we see something interesting. The eigenvalues are $\lambda_1 = \alpha + i\beta$ and $\lambda_2 = \alpha - i\beta$. We can now vary α and β and run the experiment starting each time in the synchronous state. We note values of α and β where the synchronization is stable and unstable and in that way map out the stable and unstable regions of the MSF. Figures 7 and 8 show this for an

Master Stability Function for Globally Synchronized Systems, Fig. 6 A three-oscillator system for determining the shape of the stability region for particular oscillator (F) and coupling function (H) types

Master Stability Function for Globally Synchronized Systems, Fig. 7 Contour plot of experimental probe of the MSF (x coupling). Compare to Fig. 3 (units are different, but shapes are correct)

experimental implementation of the Rössler-like oscillator circuit. You can see that the general shapes agree well with the calculations (Figs. 3 and 5, respectfully).

It turns out that although the three-oscillator network works well and has an obvious symmetry, it is only necessary to use a two-oscillator system. This was shown in the paper by Wu

Master Stability Function for Globally Synchronized Systems, Fig. 8 Experimental probe of the MSF (y coupling). Compare to Fig. 5 (units are different, but shapes are correct)

(2002). Hence, with two oscillators in an experiment and control over the coupling strengths, one can probe the MSF whose form will hold for any size and shape of network of those same oscillators and coupling functions. This is a rather remarkable result. Not much advantage has been taken of this development, but it should eventually find applications as more sophisticated, computerized experiments come online in many areas of network dynamics.

Conclusions and Remarks

Much of this review was based on results in the paper by Fink et al. (2000). There we showed that all the machineries developed here carry over to iterated maps in networks, too. One should also see the papers by Gade et al. (1995), Gade (1996), Hu et al. (1998), Boccaletti et al. (2002), Nishikawa et al. (2003), Belykh et al. (2004a, b), Chavez et al. (2005), Motter et al. (2005a, b), Belykh et al. (2006), Boccaletti et al. (2006), Zhou et al. (2006), and Belykh et al. (2008)

whose work also showed that such generalizations as the MSF might be possible in papers published at the time of our original paper on the MSF topic (Pecora and Carroll 1998). With the emphasis on network mathematics and physics starting in the late 1990s on up to today, many papers have been published that show various applications of the MSF to many different types of networks. This began with an analysis of small-world networks and synchronization (Barahona and Pecora 2002; Pecora and Barahona 2005) and continued on to analysis of synchronization under many different conditions. The topic became popular in the 2000s and continues to today.

Definition

MCell (Monte Carlo Cell) is a program for simulating spatially resolved cell models using particle-based Monte Carlo algorithms.

Detailed Description

Biological processes at the cell level take place in small and often complex geometries and frequently involve only a small number of molecular players (tens to thousands). A prime example of a process in which this “microphysiology” plays a central role is neurotransmission at chemical synapses in the brain and in the peripheral nervous system (Stiles et al. 2001; Stiles and Bartol 2001). At such small subcellular scales, the familiar macroscopic concept of concentration breaks down and stochastic behavior dominates. MCell uses optimized Monte Carlo algorithms to track discrete molecules in space and time as they diffuse and interact with other effector molecules such as membrane channels, receptors, transporters, or enzymes (Bartol et al. 1991; Stiles and Bartol 2001; Kerr et al. 2008).

The first version of MCell, released in 1995, was developed collaboratively by Tom Bartol at the Salk Institute and Joel Stiles at Cornell University for modeling chemical signaling, diffusion, and reaction of discrete neurotransmitter molecules in synaptic spaces. Version 1 of MCell supported only basic planar surfaces that represented shapes of

synaptic membranes (Stiles et al. 1996). MCell version 2, released in 1997, employed arbitrary triangulated meshes to better represent the complex geometries inherent to systems but lacked the capability to simulate diffusion on surfaces or reactions in volumes (Stiles and Bartol 2001). MCell3, the current version of MCell, was released in 2006 and is a general-purpose reaction-diffusion simulator that handles surface and volume diffusion as well as surface-surface, surface-volume, and volume-volume reactions (Kerr et al. 2008). MCell is developed and maintained by the National Center for Multiscale Modeling of Biological Systems (<http://mmbios.org>).

MCell is widely used for simulating cellular microphysiology and has been employed for computational studies of neurophysiological (e.g., Beenhakker and Huguenard 2010; Coggan et al. 2005; Nadkarni et al. 2010, 2012; Scimemi and Diamond 2012; Dittrich et al. 2013) and other cellular systems (Kerr et al. 2006; Rappel and Levine 2008). So far, more than 40 studies have been published that utilized MCell in an integral way. An up-to-date list of publications using MCell can be found on (www.mcell.org).

Software

MCell is open-source software released under a GPLv2 license and is available in both source code and binary format for the Windows, Mac, and Linux operating systems. CellBlender provides an open-source, cross-platform graphical user interface for MCell that enables a user to build, visualize, simulate, and analyze models and is available as an add-on for the open-source 3D content creation tool (<http://blender.org>). In particular, CellBlender allows the rapid creation and refinement of complex biological structures without the need for image segmentation, which can be time consuming.

Model Syntax and Components

MCell models are described using Model Description Language (MDL), which provides

grammar for defining model components (Kerr et al. 2008). These are:

1. *Initialization*: global time step, iteration number, and other user-specified model parameters.
2. *Molecule definitions*: list of participating chemical species (e.g., ions, molecules), along with their diffusion constants.
3. *Reaction definitions*: description of the biochemical interactions between the chemical species as a chemical reaction network along with reaction rate constants.
4. *Meshes*: triangulated surface meshes representing the membranes and scaffolds of a 3D cellular/subcellular domain. Meshes, which are specified using boundary representation (B-rep), can be generated in a number of ways: (i) from simple geometric primitives available in MDL, (ii) via CellBlender (or CAD tools), (iii) algorithmically by a script, and (iv) via reconstruction from electron or optical microscopy images or real tissue samples.
5. *Molecule placement*: distribution of molecules, specified in terms of densities or absolute numbers, within or on defined volume or surface domains, respectively.
6. *Output description*: counts of molecules in specified spatial domains, counts of reaction occurrences in specified spatial domains, and molecule coordinates at user-specified times over the simulation time course.

MDL also provides syntax for several advanced simulation features such as:

1. Functions for release of molecules that vary in time and space
2. Reaction-driven activation of molecule release events
3. Simulation checkpointing

The required parameters for species concentrations and reaction rates typically come from the literature, community databases, or bench experiments. Complex models can be split across any number of MDL files, which are then included from a single runnable main MDL file. The

CellBlender graphical interface allows users to build, generate, and run models without explicitly writing MDL.

Simulation

The MCell simulation kernel can be run from the command line or from within CellBlender. On start-up, MCell parses and error-checks the model description, sets the initial state of the simulation according to the user's specification, and then proceeds with the simulation. MCell provides two types of simulation output: *visualization output* contains time series of positions of molecules and meshes that can be visualized in CellBlender (see Fig. 1); *reaction data* output contains time series of molecule or reaction counts or fluxes within or on defined spatial regions of the model. Individual simulations can be stopped and restarted using MCell's checkpointing facility. An example of the visualization and video production capabilities provided by the CellBlender-MCell interface can be

seen at <http://www.youtube.com/watch?v=FZT6c0V8fW4>.

Simulation Algorithms

MCell uses optimized and validated Monte Carlo algorithms for simulating the diffusion and interaction of individual particles in 3D volumes and on 2D surfaces (see Kerr et al. 2008 for a complete description). An event-driven scheduler with adaptive time stepping handles the reaction-diffusion events as the simulation evolves in time. A particle diffusion event consists of spatial movement according to the particle's diffusion constant and the user-specified time step. The diffusion step length is computed by Monte Carlo sampling of the probability distribution function for 2D or 3D diffusion. A particle trajectory is tracked through space by ray-tracing/ray-marching algorithms, which detect collisions with membrane or scaffold surfaces and with other particles (Fig. 2). Bimolecular reaction events are driven by collisions between reactive pairs of

M

MCell, Fig. 1 Visualization of an MCell model of the frog neuromuscular junction using the CellBlender interface

MCell, Fig. 2 Particle movement and collision detection in MCell. Ray-tracing algorithms are used to detect collisions between a diffusing particle along its direction of motion and other particles or surfaces. Ray marching is used to propagate rays following collisions, such as those involving a reflective surface as illustrated here. Molecules within the shaded tube of radius r_{int} around the trajectory (and on the near side of the surface) are collision partners, which are checked in sequence of encounter to determine whether a reaction occurs. For further details, see Kerr et al. (2008)

particles. The bimolecular reaction rate constants specified by the user are converted to per collision reaction probabilities, and a random number generator is used to determine whether a given collision results in a reaction in accordance with this probability. Unimolecular reaction events are scheduled by sampling the exponential distribution of particle state lifetime corresponding to the rate constant of the unimolecular reaction.

Future Developments

The MCell development team is currently actively working on several advanced new simulation features, which will be made available in future MCell releases. These include import/export of SBML models, import of rule-based models, parallelization, dynamic model geometries, and space-filling particle diffusion approaches.

Acknowledgments We gratefully acknowledge the funding from NIH/NIGMS grant P41GM103712. In addition we thank Jacob Czech for his help with the figure preparation; the members of the MCell development team, including Dipak Barua, Jacob Czech, Leonard Harris, Bob Kuczewski, and Jose Juan Tapia, for the helpful discussions;

and Terry Sejnowski for the support and inspiration. We dedicate this entry to the memory of Joel R. Stiles.

[Models of mechanoreceptive afferents](#)

Definition

Computational models of mechanotransduction describe how somatosensory receptors respond to stimuli applied to the skin. There are two distinct approaches to this problem: (1) modeling skin mechanics and transduction and (2) modeling single neuron spike generation. The first type of model describes how the skin is deformed by a tactile stimulus and how this deformation leads to a neuronal response. These models of skin mechanics and transduction can be further divided into two distinct subcategories: those based on continuum mechanics and those based on finite element analysis. The second type of model focuses on the biophysics of spike generation in single neurons. It usually consists of two stages: a transduction stage and an integrate-

and-fire (IF) stage. The transduction stage describes the conversion from skin deformation into a current injection into the neuron, while the IF stage simulates the generation of action potentials. Under some circumstances, these models can predict the precise temporal structure of the spiking activity with millisecond-level precision.

Combined skin mechanics models and biophysical spike-generation models can account for the gamut of spatiotemporal transformations that occur at the somatosensory periphery including the spatial filtering properties of the skin and the nonlinearities and dynamics of transduction and spike generation.

Detailed Description

Tactile Sensation

Tactile sensation and the haptic manipulation of objects begin with the activation of mechanoreceptors embedded in the skin. The skin itself is composed of viscoelastic media and deformed by contact with external stimuli (Lanir 1987). Forces applied to the skin elicit the flow of electrical currents into mechanoreceptors. Three types of mechanoreceptors innervate primate glabrous skin: slowly adapting type 1 (SA), rapidly adapting (RA), and Pacinian (PC) afferents (Gescheider et al. 2004; Hsiao and Bensmaia 2008; Johansson 1978; Johnson 2001; Pare et al. 2002; Talbot et al. 1968). These afferents respond to different aspects of skin deformation. SA afferents are sensitive to static indentations and to low-frequency skin vibrations. These afferents encode the shape of an object grasped in the hand. RA afferents are most responsive to skin vibrations at the flutter frequencies (10–40 Hz), commonly generated when an object moves across the skin or slips from one's grasp (Johansson and Westling 1987; Srinivasan et al. 1990). These afferents also produce a robust transient response at the onset and offset of contact with an object. PC afferents mainly respond to high-frequency vibrations generated, for example, during scanning of textured surfaces. Importantly, mechanoreceptive responses of all three types are highly repeatable and precise, and this millisecond-precision spike

timing shapes the way stimuli are perceived (Johansson and Birznieks 2004; Mackevicius et al. 2012).

Classes of Models

Mechanotransduction models were developed to better understand the biophysics of touch. As mentioned above, there are two general classes of models: (1) models of skin mechanics and (2) biophysical receptor models. Models of skin mechanics are based on continuum mechanics (Oomens et al. 1987; Phillips and Johnson 1981; Sripati et al. 2006) or finite element analysis (Dandekar et al. 2003; Gerling and Thomas 2008; Larrabee Jr and Galt 1986; Wu et al. 2004) and are intended to estimate the impact of skin deformations on mechanoreceptors. On the other hand, biophysical receptor models provide a simplified representation of the transduction and spike-generation process (Dong et al. 2012; Freeman and Johnson 1982; Kim et al. 2010, 2012;). Here, we describe a representative skin mechanics model based on continuum mechanics (Sripati et al. 2006) and a receptor model based on integrate-and-fire mechanism (Dong et al. 2012). Finally, we will show how these models can be combined for other applications.

A Model of Skin Mechanics

The skin mechanics model summarized here (Sripati et al. 2006) is based on continuum mechanics. The purpose is to estimate 3D stress/strain profiles produced by a stimulus and to then predict the response of mechanoreceptive afferents based on these profiles. The model includes two computational steps. First, the forces exerted by the stimulus on the skin are computed from the spatial profile of the stimulus (Phillips and Johnson 1981). Second, the stresses and strains experienced by the receptors in the skin are computed from the skin deformation profile.

To determine how the skin is displaced by the stimulus, the model begins with the assumption that the skin touches the entire surface of stimulus. In reality, some parts of the stimulus do not touch the skin (imagine a toy rubber stamp on your finger). To determine which parts of the stimulus do not touch the skin, an algorithm (see Eq. 1 below) identifies parts of the stimulus that yield negative forces. In other words, this skin area would need to be pulled towards these regions of the stimulus in order for the skin to conform to them (thus the negative forces). Hence, this area is simply removed from further consideration. The force calculation and exclusion of areas with negative force is computed iteratively until the resulting stimulus yields no negative forces (see Sripati et al. 2006 for more details).

The forces exerted on the skin, are given by solving the following equation for (Phillips and Johnson 1981):

$$S = CP \quad (1)$$

where S is a vector describing the skin deformation pattern or, equivalently, the stimulus pattern. C is a matrix providing a mapping between force and displacement: element (i, j) represents the displacement at position i when a unit force is applied at location j :

$$C_{ij} = \frac{(1 - \nu^2)}{\pi E r_{ij}} \quad (2)$$

where E is the modulus of elasticity, ν is Poisson's ratio (set to 0.4; cf. Wu et al. 2004), and r_{ij} is the distance between locations i and j (Timoshenko and Goodier 1969). As described above, if any elements of P are negative, corresponding elements of Eq. 1 are excluded from subsequent calculations.

In the second step, the stress tensor with six components (three normal forces and three shear forces in 3D space) can be easily computed for a given three-dimensional point in the skin (Timoshenko and Goodier 1969):

$$\sigma = \begin{bmatrix} \sigma_r & \sigma_{r\theta} & \sigma_{rz} \\ \sigma_{r\theta} & \sigma_\theta & \sigma_{\theta z} \\ \sigma_{rz} & \sigma_{\theta z} & \sigma_z \end{bmatrix} = \frac{P}{2\pi} \begin{bmatrix} \frac{3r^2 z}{R^5} - \frac{1-2\nu}{R^2 + zR} & 0 & \frac{3rz^2}{R^5} \\ 0 & (1-2\nu)\left(\frac{1}{r^2} - \frac{z}{r^2 R} - \frac{z}{r^3}\right) & 0 \\ \frac{3rz^2}{R^5} & 0 & \frac{3z^2}{R^5} \end{bmatrix} \quad (3)$$

where, in Cartesian coordinates, $r = \sqrt{x^2 + y^2}$, $R = \sqrt{r^2 + z^2}$, and z are the axes perpendicular to the skin surface. The stress profile is then computed, in Cartesian coordinates, and summed

across all deformed skin positions, using the coordinate transformation method (Timoshenko and Goodier 1969):

$$\begin{bmatrix} \sigma_x & \sigma_{xy} & \sigma_{xz} \\ \sigma_{xy} & \sigma_y & \sigma_{yz} \\ \sigma_{xz} & \sigma_{yz} & \sigma_z \end{bmatrix} = \begin{bmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \sigma_r & \sigma_{r\theta} & \sigma_{rz} \\ \sigma_{r\theta} & \sigma_\theta & \sigma_{\theta z} \\ \sigma_{rz} & \sigma_{\theta z} & \sigma_z \end{bmatrix} \begin{bmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (4)$$

Finally, the strain tensor (ϵ) can be then obtained using Hooke's law:

$$\epsilon_{ij} = \frac{1+\nu}{E} \sigma_{ij} - \frac{\nu}{E} (\sigma_x + \sigma_y + \sigma_z) \delta_{ij} \quad (5)$$

where δ_{ij} is the Kronecker delta function.

A Biophysical Model of Transduction

Given the importance of spike timing in somatosensory processing (Johansson and Birznieks 2004; Mackevicius et al. 2012), a mechanoreceptor model must reproduce neural activity with great temporal accuracy. Early attempts to model mechanoreceptive afferents using an integrate-and-fire model showed that some key features of the fine temporal structure of afferent responses (in addition to the strength of their response) can be captured using such a modeling framework (Freeman and Johnson 1982). Recent models incorporated known properties of mechanoreceptors to make them more versatile:

1. All three afferents have been shown to rectify or partially rectify time-varying stimuli (Bolanowski Jr and Zwislocki 1984; Whitsel et al. 2000). For example, some afferents

respond only to the indentation phase of a sinusoidal skin vibration, while others respond to both the indentation and retraction phase.

2. All three afferents are differentially sensitive to indentation depth and/or its derivatives (velocity and acceleration) (Kim et al. 2010; Loewenstein and Skalak 1966; Pubols Jr 1980).
3. Afferent responses saturate when stimulated at high intensities (Johnson 2001).
4. Different mechanoreceptive afferents exhibit differential sensitivity to stimulus frequency (Freeman and Johnson 1982; Muniak et al. 2007; Talbot et al. 1968).

The model summarized here (Dong et al. 2012) involves two stages (Fig. 1). In the first stage, the stimulus and its derivatives are rectified and summed with different weights. In the second stage, the output of the first stage is passed through a saturation filter and fed into a generalized integrate-and-fire model (Mihalas and Niebur 2009), which generates spikes. The transduction stage is described as

$$s(t) = \sum_{i=0}^2 w_i^+ s_i^+(t) + w_i^- s_i^-(t) \quad (6)$$

$$I(t) = \frac{I_0 s(t)}{I_0 + |s(t)|} \quad (7)$$

where $s_i^+(t)$ and $s_i^-(t)$ are the rectified positive and negative components of the i th derivative of the skin deformation depth (with s_o the depth itself), respectively, and w_i^+ and w_i^- are free parameters (see Fig. 1). I_0 is a free parameter that determines the degree of saturation. In total, there are seven free parameters in the transduction stage. Then, the integrate-and-fire model stage is governed by the following equation:

$$V'(t) = -\frac{1}{\tau}(V(t) - V_{rest}) + \frac{I(t) + I_{ind}(t)}{C} \quad (8)$$

$$\Theta'(t) = a(V(t) - V_{rest}) - (\Theta(t) - \Theta_\infty)/b \quad (9)$$

where C , V_{rest} , Θ_∞ , and b represent capacitance, resting membrane potential, equilibrium threshold, and threshold rebound time constant (that allows for long-term adaptation), respectively. Equation 8 describes the leaky integration of the injected current, and Eq. 9 computes the time-varying threshold of the neuron. For some of these variables, we used fixed values: $C = 150$ pF, $V_{rest} = -70$ mV, $\Theta_\infty = -30$ mV, and $b = 0.1$ s derived from the literature. The free parameters of the model include ς and τ , the threshold adaptation constant for short-term

adaptation and the membrane time constant, respectively. A spike-induced current, $I_{ind}(t)$, accounts for refractoriness and consists of two types of inhibitory ion channels (i_0 and i_1) with different decay time constants, $\tau_0 = 5$ ms and $\tau_1 = 50$ ms:

$$\begin{aligned} I_{ind} &= i_0 + i_1 \\ \frac{di_0}{dt} &= -\frac{i_0}{\tau_0} \\ \frac{di_1}{dt} &= -\frac{i_1}{\tau_1} \end{aligned} \quad (10)$$

When $V(t)$ reaches $\Theta(t)$, the membrane voltage and the threshold are reset to V_{reset} and $\max(\theta(t), \Theta_\infty)$, respectively, and a spike is generated, which, in turn, induces currents through two ion channels:

$$\begin{aligned} i_0 &\leftarrow i_0 + A_0 \\ i_1 &\leftarrow i_1 + A_1 \end{aligned} \quad (11)$$

where A_0 , A_1 are free parameters representing the initial amplitudes of the spike-induced currents, which decay away with time constants, τ_0 and τ_1 . Finally, the transduction delay is the last additional free parameter, resulting in a total of 12 free parameters in the model. The small number of parameters (compared to hundreds in an older model proposed by Kim et al. 2010) yields a model that generalizes well. That is,

Mechanotransduction, Models, Fig. 1 Model of mechanotransduction. The time-varying skin indentation and its derivatives are computed in real time. The weighted

sum of rectified signals is fed into the MN model (Mihalas and Niebur 2009) through a saturating filter

Mechanotransduction, Models, Fig. 2 Responses of a typical SA, RA, and PC afferents to complex time-varying skin deformations and corresponding model predictions. *Black* rasters show the measured spiking responses to five repeated presentations of each stimulus, and the *red* rasters

show the predicted responses. The first and second rows show response to diharmonic stimuli used to fit the model. The third row shows responses to band-passed noise stimuli that were not used to train the model

Mechanotransduction, Models, Fig. 3 Measured and predicted rate-intensity functions in response to sinusoids for an SA, RA, and PC afferent. *Red dots* represent the average number of spikes evoked on each stimulus cycle.

Solid blue lines show the predicted response rate, and the *dashed blue lines* show the model prediction without the saturation filter

good performance of the model on the training data generally leads to good performance on novel stimuli.

The model can be efficiently fit to observed physiological neural activity by minimizing a cost function defined by

$$F = \sum_i 1 - e - \log (T_{\tau n}^i / T^i)^2 \quad (12)$$

Mechanotransduction, Models, Fig. 4 Simulated response to a letter scanned across the skin. The displacement profile of the letter “G” is first converted into a strain profile using a skin mechanics model (*heat map*). Each row of this profile represents a single scan across the skin (scanning is from *left to right*). The time-varying strain is then fed into the mechanotransduction model, which generates spikes, shown as rasters superimposed on the strain profile. These model-predicted spiking responses are almost identical to their measured counterparts (Kim et al. 2010; Phillips et al. 1988)

where T^i is the i th observed spike time interval and T_m^i is the corresponding spike interval of the model (see Dong et al. (2011) for details).

Figure 2 shows an example of each afferent type responding to two diharmonic and noise stimuli. Note that diharmonic stimuli were used to train the model, whereas noise stimuli were used to test it. For these stimuli, the model predictions were matched with the observed response with millisecond-level accuracy. The model also captures the characteristic piecewise linear rate-intensity function to sinusoidal stimuli (Freeman and Johnson 1982; Johnson 1974; Muniak et al. 2007; Fig. 3). Finally, the model captures the response saturation property, most prominent in PC afferents.

Application

Given its ability to predict afferent response to novel stimuli with millisecond precision, the model can be used in a variety of applications (Kim et al. 2009, 2010; Russell et al. 2009). In scientific applications, the model can be used to simulate neural responses and thus obviate the need to perform neurophysiological studies, which are time consuming and require the sacrifice of animals. Skin mechanics models can be integrated with integrate-and-fire models to simulate the afferent responses to

Mechanotransduction, Models, Fig. 5 An example of a neuroprosthesis with a peripheral nerve interface. The motor command from the brain is delivered to the actuators via the spinal cord. Then a matrix of touch sensors embedded in the artificial skin detects the contact with objects.

This signal is transformed into spike timings using embedded computer. Finally, the residual nerve of the patient is stimulated electrically or through optogenetics

arbitrarily complex spatiotemporal patterns of skin deformation. First, the skin mechanics model generates a skin strain profile at each time step based on the indentation profile, which in turn can be used as input to the biophysical model described. For example, the well-documented response of a population of SA afferents to a letter scanned across the skin can be reproduced using this approach (Fig. 4; Kim et al. 2010).

For a more medically oriented application, these models can be used to convey sensory feedback in upper-limb neuroprostheses. Specifically, they can be used to convert the output of force sensors embedded in upper-arm neuroprostheses into naturalistic patterns of activation (Fig. 5; Kim et al. 2009), effected in the nerve through electrical (or perhaps someday optogenetic) stimulation. The model itself can be implemented in a semiconductor chip in a computationally effective way because of its small number of parameters and simple structure to allow for real-time artificial transduction. Even analog silicon chips could be used for maximum integration (Indiveri et al. 2011). Furthermore, if the integration time window of upstream structures is long enough (>25 ms), a single canonical parameter set for each afferent type can be used for all embedded sensors, which vastly simplifies device production (Kim et al. 2011).

[Hippocampal memory decoding model](#)

Definition

Memory decoding model is a computational model that maps neural signals to memories (Fig. 1). It can be used to investigate memory encoding and retrieval processes in the brain.

Detailed Description

Memory decoding models can take many different forms. In a human hippocampal memory decoding model, hippocampal CA3 and CA1 spike trains are recorded from human subjects performing a delayed match-to-sample (DMS) task (Fig. 2), in which subjects are required to remember sample images after a delay. Within the DMS task, memory encoding is defined as

Memory Decoding

Model, Fig. 1 Structure of the hippocampal memory decoding model. Model inputs are spatio-temporal patterns of hippocampal spikes. Model outputs are memory labels related to features and categories of sample images. Neural activity features are extracted with B-spline basis functions. The classifier takes the form of a sparse logistic regression classifier

M

Memory Decoding Model, Fig. 2 Delayed match-to-sample (DMS) task. A DMS trial starts with a circle cue presented on the touchscreen. In the Sample Phase, the patient touches an image presented in a specific position

of the screen. In the Match Phase, the patient needs to choose and touch the correct image that he has seen in the Sample Phase among distractors to generate a correct response

the mapping from sample images to hippocampal spike trains, while memory decoding becomes the prediction of sample images from hippocampal spike trains (Song et al. 2014, 2016, 2017). The

modeling task is formulated as building a classifier that predicts categories and features of sample images based on spatio-temporal patterns of hippocampal spike trains (Fig. 1).

B-spline basis functions are used to extract neural activity features from spatio-temporal patterns of spikes (Song et al. 2013, 2014). B-splines are piecewise polynomial functions with smooth transitions between adjacent pieces at a set of interior *knot* points. The number of knots J , controls the temporal resolution of B-splines. Given a B-spline basis B , spike trains x are projected to the B-spline feature space via an inner product to yield feature vectors z as

$$z^{(n)}(j) = \sum_{\tau_1}^{\tau_2} B_j(\tau) x_n(\tau) \quad (1)$$

Interval $[\tau_1 \tau_2]$ is the time window for the inner product, which is chosen to be from -2 s to $+2$ s of the Sample Response events. Variable x_n is the n th neuron of the N neurons included in the analysis. J is the number of B-spline basis functions.

Images presented in the sample phase are labeled by normal human subjects with 29 non-mutually exclusive categories and features: Cartoon, Photo, Black & White, Color, Red, Orange, Yellow, Green, Blue, Activity, Animal, Artifact, Building, Geometric Shape, Human, Landscape, Plant, Tool, and Vehicle. This procedure provides the target signal for the classification model. Therefore, the model output is simplified as a binary variable β . The classification model based on logistic regression can be expressed as

$$P(\beta = 1|x) = \left[1 + \exp \left\{ -w_0 - \sum_{n=1}^N \sum_{j=1}^J w^{(n)}(j) z^{(n)}(j) \right\} \right]^{-1} \quad (2)$$

$$P(\beta = 0|x) = 1 - P(\beta = 1|x) \quad (3)$$

Variable w are the sought classification model coefficients; 1 and 0 represent positive and negative labels, respectively. The linear classification rule becomes

$$\beta = \begin{cases} 1 & \text{if } \left\{ -w_0 - \sum_{n=1}^N \sum_{j=1}^J w^{(n)}(j) z^{(n)}(j) \right\} < 0 \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

This classification model often suffers from a serious overfitting problem due to the super high-dimensional input and the relatively small number of data points. $L1$ regularization (Lasso) is applied to achieve sparse model estimation and avoid overfitting as (Song et al. 2013, 2014)

$$S(w) = -l(w) + \lambda \left(\sum_{n=1}^N \sum_{j=1}^J \|w^{(n)}(j)\|_2^1 \right) \quad (5)$$

$-l(w)$ and λ are the negative log likelihood function and the tuning parameter, respectively. By minimizing S with a n -fold cross-validation method, λ is optimized and w is estimated.

For a given B-spline knot sequence, the sparse classification function matrix (SCFM) F can be reconstructed with w and B as

$$F^{(n)}(\tau) = \sum_{j=1}^J B_j(\tau) w^{(n)}(j) \quad (6)$$

F can be directly used to calculate the conditional probability of the modeled label with the input spatio-temporal pattern x as

$$P(\beta = 1|x) = \left[1 + \exp \left\{ -w_0 - \sum_{n=1}^N \sum_{t=1}^M F^{(n)}(\tau) x^{(n)}(t) \right\} \right]^{-1} \quad (7)$$

The performance of each model is evaluated with the Matthews correlation coefficients (MCCs). MCC is robust to unbalanced data and can be calculated from the confusion matrix as

$$MCC = \frac{TP \times TN - FP \times FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}} \quad (8)$$

TP , TN , FP , and FN are the numbers of true positives, true negatives, false positives, and false negatives, respectively. The MCC value is between -1 and 1 . MCCs of 1 , 0 , and -1 represent perfect prediction, no better than random prediction, and completely opposite prediction, respectively.

Memory Decoding Model, Fig. 3 Decoding memory features and categories from hippocampal spike trains using the memory decoding model. Each color represents one patient ($n = 8$)

Applications

The memory model can be used as a computational tool to investigate memory encoding and retrieval processes in brain regions such as the hippocampus. Furthermore, it can also be used to design stimulation patterns for testing the effectiveness of neural code-based electrical stimulation in facilitating memory formations (Song et al. 2017). Such experiments have crucial implications for the development of hippocampal memory prostheses for restoring and enhancing memory functions (Hampson et al. 2018; Song et al. 2007, 2014, 2018).

Human studies have shown that multiple memory features and categories can be decoded from hippocampal CA3 and CA1 spike trains (Fig. 3). These memory decoding results support the hypothesis that episodic memories are formed in the hippocampus and encoded in the hippocampal activities.

Definition

For the purposes of constructing biologically plausible neural population and field models of cortical activity, it is necessary to take into account the anatomical and histological

organization of the cortex that is intermediate in scale between that of the single neuron and the whole brain. The anatomy of the intermediate, or mesoscopic, level of cortical organization is defined by the variety of neuronal and non-neuronal cellular components, their spatial disposition and organization, and the structural features of their bulk connectivity.

Detailed Description

The thin outer rind of the mammalian brain, the neocortex, is generally thought to be the principal structure responsible for the generation and elaboration of purposeful activity. For a structure that is between 1 and 5 mm thick and has a surface area of only $\sim 0.19 \text{ m}^2$ (Van Essen 2005) in humans, it has an unparalleled degree of structural complexity with the $\sim 2 \cdot 10^{10}$ neurons (Pakkenberg and Gundersen 1997) broadly divided into six horizontal layers and with at least a dozen major neuronal subtypes (Markram et al. 2004), interacting with each other via synaptic connections with other neurons (Tang et al. 2001), synapses that utilize an array of chemical messengers and can be individually modified. Fortunately, the mammalian cerebral cortex is sufficiently well organized over a number of relatively distinct spatial scales to enable the meaningful construction of neural population models.

Cellular Composition of the Neocortex

The cortex is comprised of neuronal and non-neuronal components with the neurons being broadly classified as belonging to two types: pyramidal and non-pyramidal cells. The nonneuronal components of cortical tissue can be divided into the neuroglia and the cells of the perforating blood vessels. The neuroglia are comprised of astrocytes, microglia, oligodendrocytes, and ependymal cells.

Pyramidal cells are the most numerous neuronal class making up somewhere between 60% and 85% (Braitenberg and Schüz 1998; Nieuwenhuys et al. 2008) of all cortical neurons. A typical

pyramidal neuron is composed of a cell body from which a single axon descends and branches intracortically before exiting the cortex to travel subcortically, as the cortico-cortical fibersystem, to terminate in distant cortical areas. The dendritic tree is composed of two main branching structures: an apical dendritic tree composed of a trunk ascending in the direction of the pial surface and a basal dendritic tree composed of multiple trunks giving rise to a cloud of local dendritic branches about the cell body. Both dendritic structures are typically extensively covered with small excrescences called spines where synapses form (Spruston 2008). Cylindrical groupings of the apical dendrites of 50 or so pyramidal neurons constitute a core component of the hypothesized *minicolumn*: a barrel-shaped region representing the basic modular unit of the neocortex (Rockland and Ichinohe 2004). While pyramidal neurons generally show a fair degree of morphological variability, the only atypical variant is the spiny stellate cell, an excitatory interneuron which lacks the characteristic ascending apical dendritic tree and descending axon. Pyramidal neurons constitute a functionally homogeneous group as they all exclusively release the excitatory monoamine glutamate from their axonal terminals.

Non-pyramidal cells are a morphologically much more differentiated class of cortical neuron that have a number of features in common (Nieuwenhuys et al. 2008): their dendrites are often spine-free, their axons do not leave cortex (hence often called *local circuit* or *interneurons*), most release the inhibitory neurotransmitter γ -amino butyric acid (GABA), and a certain fraction (25–30%) also express one or more neuropeptides such as vasoactive intestinal polypeptide (VIP) or cholecystokinin, and various subpopulations show differential immunoreactivity to one or more intracellular calcium-binding proteins which can be used as subpopulation-specific markers. It has been estimated that a dozen or so non-pyramidal cell subtypes can be identified morphologically (Markram et al. 2004), the most numerous of which are basket cells. Other notable non-pyramidal cells include the chandelier, bipolar, and double-bouquet cells.

Laminar Organization of the Neocortex

The cerebral cortex can be divided into vertically stacked cellular laminae extending through the thickness of the cortex. The number, size, and organization of these layers show substantial regional/areal variation. Developmentally two broad structural forms of the cerebral cortex can be identified – homogenetic and heterogenetic cortices.

Homogenetic cortex, commonly referred to as neocortex or isocortex, makes up the bulk of the cerebral cortex and either consists of six reasonably well-defined cellular laminae (homotypical cortex) or began as a well-defined six-layered cortex, but during development the addition or elimination of layers occurred (heterotypical cortex). Heterogenetic cortex (also known as allocortex) is divided into primitive (or paleo-) cortex, in which there is no clear laminar cellular organization (e.g., olfactory bulb), and rudimentary (or archi-) cortex, in which there are only the crude beginnings of lamination (e.g., hippocampus).

The six neocortical layers, typically labeled I–VI (superficial–deep), are characterized by variations in cellular densities, types, and morphologies as well as the patterns of termination and generation of cortical and subcortical afferents and efferents. Non-pyramidal cells occur in all layers and pyramidal cells in layers II to VI. Layer IV of sensory cortices is notable for the large numbers of tightly packed spiny stellate neurons, which are only found there, and the termination of sensory thalamocortical afferents on these neurons and the dendrites of other neurons passing through this layer (Thomson and Bannister 2003). In contrast it has been observed that associational and callosal cortico-cortical efferents arising from layer II and III pyramidal neurons preferentially terminate in layer IV, whereas layer V/VI pyramidal neuron long-range axons preferentially terminate in layers I and VI (Rockland and Pandya 1979).

A variety of attempts have been made to systematically classify variations in the cellular architecture of the various neocortical laminae (cytoarchitectonics) over the whole cerebrum. The most important of these is the architectonic

parcellation scheme of Brodmann (Brodmann and Garey 2006).

Modular Organization of the Neocortex

Commencing with the work of Lorente de No, who first proposed that a small radially oriented cylinder of cells extending through the full extent of the cortex with a single thalamocortical axon as its axis defined an *elementary unit* of neocortical organization, the intervening years have seen a variety of attempts to define a *basic modular unit* of cortical organization.

Amongst the most well known are the micro-, mini-, macro-, and cortico-cortical columns. Micro- and minicolumns typically refer to radially organized chords of ≈ 10 –200 cells that span layers II to VI, arranged as horizontal mosaics with periodicities of the order of 15–80 μm (Jones 2000; Buxhoeveden and Casanova 2002; Rockland and Ichinohe 2004; Nieuwenhuys et al. 2008).

Macrocolumns, first hypothesized by Mountcastle (1957) on the basis of electrophysiological evidence, are thought to be anatomically comprised of aggregations of several 100 minicolumns bound together by short-range horizontal excitatory and inhibitory connections (Mountcastle 1997). Cortico-cortical columns (also referred to as neocortical columns) are typically defined in terms of the cylindrical aborization volumes of either a single afferent cortico-cortical fiber or closely packed bundles of such fibers (Jones et al. 1975; Goldman and Nauta 1977; Szentágothai 1983). Estimates of the radial extent of such columns vary from 200 to 800 μm .

While some areas of cortex have a greater claim to displaying some form of columnar organization than others, visual and somatosensory in particular, cortical columns of any form or variety have not been substantiated by unequivocal anatomical evidence and therefore remain hypothetical. Neocortical columns (Markram 2008), intensely studied in barrel cortex (Petersen 2007; Lübke and Feldmeyer 2007), are perhaps closest to being established.

Mesoscopic Anatomy and Neural Population Models, Table 1 Major structural units of organization in mammalian neocortex and their approximate

characteristics, see text. For neuronal groupings the diameter of a disk with equivalent cortical surface area is given as scale

	Unit	Neurons per unit	No. of units ^b	Scale
Micro	Neuron (soma)	1	$2 \cdot 10^{10}$	15 μm
	Microcolumn ^a	20	10^9	15 μm
	Minicolumn	100	$2 \cdot 10^8$	35 μm
Meso	Dendritic tree	–	–	0.15 mm
	Cortico-cortical column	10^4	$2 \cdot 10^6$	0.35 mm
	Intracortical axonal tree	–	–	0.5 mm
	Macrocolumn	$2 \cdot 10^5$	10^5	1.5 mm
	Martinotti axonal tree	–	–	2 mm
Macro	Architectonic area	$2 \cdot 10^8$	100	5 cm ^b
	Cortico-cortical axon	–	–	10 cm ^b
	Brain region	$2 \cdot 10^9$	10	15 cm ^b
	Neocortex	$2 \cdot 10^{10}$	1	50 cm ^b

Table reproduced from Liley et al. (2012)

^aThe term “microcolumn” is sometimes used to refer to our “minicolumn”

^bFigures are given for the human neocortex

The neocortex consists of populations of vertically well-connected cellular elements interacting horizontally over a range of spatial scales. In general it is the lateral intra- and cortico-cortical axonal ramifications of neocortical pyramidal neurons that define the spatial scales of horizontal connectivity within the neocortex. The lateral axonal ramifications of certain interneurons (e.g., layer II/III double-bouquet cells, Martinotti cells) provide additional characteristic scales for the horizontal organization of the cerebral cortex.

Table 1 summarizes the various scales of cortical organization that have been identified or proposed on the basis of anatomical evidence.

Meta-analysis in Neuroimaging

Kimberly Ray¹ and

Angela Marie Richmond Laird²

¹Research Imaging Institute, University of Texas Health Science Center, San Antonio, TX, USA

²Department of Physics, Florida International University, Miami, FL, USA

Definition

Meta-analysis is the post hoc combination of experimental results from independently performed neuroimaging studies to better estimate a parameter of interest.

Detailed Description

Meta-analysis

The advent of neuroimaging has resulted with an abundance of data localizing the neural effects of specific mental processes in both healthy and clinical populations. To ease the burden of interpretation and consistency across studies, standards of spatial normalization and the reporting of peak activation locations in stereotactic coordinates based upon a standardized atlas space have been

accepted community-wide. As an alternative to image-based databases, mining coordinate-based data has also yielded new insight into functional connectivity in the human brain (Toro et al. 2008; Smith et al. 2009; Laird et al. 2011). In the context of coordinate-based archives, the 3D stereotactic coordinates of significant functional activations can be archived along with metadata describing subjects, task or paradigm, including behavioral conditions, and standard brain template. The two largest and most commonly known coordinate-based databases are the BrainMap database (brainmap.org; Fox and Lancaster 2002; Laird et al. 2005a; Fox et al. 2005) and Neurosynth (Neurosynth.org; Yarkoni et al. 2011).

The BrainMap database separates functional and anatomical articles into two separate databases. Each paper is manually coded and reviewed by faculty to maintain accuracy and consistency of the entries. Information that is coded along with the coordinates provides a description of how the activations were derived from the subjects. This metadata is based on an expert-generated taxonomy that has been refined over the past 15 years and is the basis for the Cognitive Paradigm Ontology (Turner and Laird 2011). In contrast, *the Neurosynth database* provides an automated annotation of the literature. Because of the automated labeling of experimental results, Neurosynth combines functional and anatomical experiment coordinates and tags each paper with a set of terms that frequently occur within the text.

Both the BrainMap database and the Neurosynth database have been shown to be extremely useful for meta-analysis in which sets of coordinates are pooled to search for spatially consistent regions of brain activity (Niendam et al. 2012; Zald et al. 2012; Turkeltaub et al. 2002). In general, the term “meta-analysis” often refers to a variety of methods focused on combining the post hoc results from independently performed studies to better estimate a parameter of interest (Fox et al. 1998). In the field of neuroscience, localized neural activity is the parameter of interest, and quantitative, coordinate-based meta-analytic methods are often preferred over the historically qualitative literature review. These reviews can be quite time consuming, are substantially less precise, and often are susceptible to sampling bias.

Coordinate-based meta-analysis algorithms, on the other hand, have been statistically refined and enhanced for the last ten years and are now widely accepted within the neuroimaging community. One of the most common algorithms for coordinate-based meta-analyses is activation likelihood estimation (ALE; Turkeltaub et al. 2002; Laird et al. 2005b; Eickhoff et al. 2009) which treats reported foci as not as points but as spatial probability distributions centered at the given coordinates. This method is supported by the BrainMap project and can be applied to a set of activation foci using the GingerALE application (brainmap.org/ale). Other commonly used coordinate-based meta-analysis algorithms in neuroimaging include the *kernel density analysis* (KDA; Wager et al. 2004), *multilevel kernel density analysis* (MKDA; Wager et al. 2007), and signed differential mapping (Radua et al. 2012).

Definition

G protein-coupled receptors (GPCRs) are a large and important class of eukaryotic membrane receptors that bind extracellular ligands (molecules as diverse as odorants, hormones, pheromones, photons, neurotransmitters, and small molecule drugs) and transmit those cues to networks of intracellular signaling molecules ultimately driving and modulating cellular response. Mathematical modeling of GPCR signaling provides a platform to elucidate the mechanisms by which GPCR signaling carries out normal cellular function and, in disease states, what aspects of the system are perturbed.

Detailed Description

The wide variety of GPCR receptor species (>800 genes (Venter et al. 2001; Howard et al. 2001)), their diverse cellular responses, and their location at the cell membrane make GPCRs an ideal target for pharmacological intervention in disease states. In fact 30–40% of all current pharmaceuticals target GPCRs (Overington et al. 2006; Howard et al. 2001). GPCRs activate membrane-associated heterotrimeric G proteins, which then initiate signaling of the phosphatidylinositol (IP) and cyclic adenosine monophosphate (cAMP) pathways. GPCRs also participate in non-G protein-associated signaling through G protein-coupled receptor kinases (GRKs), Src kinases, arrestin binding, and PDZ domain-containing proteins (Magalhaes et al. 2012; Romero et al. 2011; Shenoy and Lefkowitz 2011). In addition, the dynamics of GPCR-mediated cellular responses are modulated by multiple ligand-dependent and cellular-dependent phenomena including ligand affinity, efficacy, receptor oligomerization, receptor trafficking (internalization and recycling, localization into

lipid rafts), receptor desensitization by phosphorylation and arrestin binding, and nonlinear feedback and cross talk events within the signaling network. Taken together it is difficult, if not impossible, to intuit the contribution of so many kinetic processes to GPCR-dependent cellular behavior. Mathematical modeling offers a tool by which these mechanisms can be examined, parsed, and understood.

As with all modeling efforts, the techniques employed to investigate different aspects of GPCR signaling vary in their specificity and complexity, from techniques that are meant to focus on network topology and connections (principal component analysis, directed graphs, Bayesian networks, and fuzzy logic) to deterministic models that include regulatory mechanisms, rates of change in concentration, and spatial location of biochemical species (ordinary and partial differential equations) to models tracking the movement of individual biomolecules (probabilistic agent-based and stochastic models). In constructing a computational model of a system, the details that are included depend on the questions being asked, the level of details known, the timescale involved, and a variety of other assumptions about the system under study (for more details on GPCR models, see (Linderman 2009)).

A critical aspect of computational modeling is model validation. Models are built on simplifying assumptions and parameters that are not always known or that have significant uncertainty. Therefore, it is important to validate the assumptions and parameters by:

- Experimentation and measurement
- Extensive literature searches
- Parameter fitting

Expanding the analysis by running simulations under varying assumptions and initial conditions builds intuition about how parameters of the system interact to determine system behavior. Developing models with the goal of making experimentally testable predictions serves to consolidate information, test hypotheses, and provide insight into previously held notions about signaling mechanisms.

While specific models of GPCR systems in neuroscience are sparse, the ubiquity of GPCRs across cell and tissue types allows researchers to adapt previously published models to particular neuro-systems of interest. The next sections discuss general classes of modeling techniques that have been used with great effect in understanding different aspects of GPCR signaling and function not necessarily restricted to traditional neuronal systems.

Equilibrium models describe how perturbations of a system change the distribution of the states of model species, for example, how addition of a ligand changes the distribution of receptor states. They are built using algebraic equations and assume that dynamic changes in redistribution are rapid relative to the timescale of interest. The dynamics of the redistribution itself is not under investigation. They have limited use in describing the inherent dynamic behavior of intracellular signal transduction but have been applied with great utility to describe pharmacological phenomena of ligand efficacy, allosteric modulation, and receptor states observed in GPCR systems (Kenakin 2002; Monod et al. 1965).

Kinetic models of GPCR signaling are used to examine the mechanisms that drive the dynamic behavior of GPCR activation, downstream protein-protein interactions, and receptor regulatory mechanisms (phosphorylation, desensitization, and receptor endocytosis and recycling). In these models, signaling events are described by systems of differential equations in which protein-protein interactions are governed by binding and dissociation rate constants (“ k_{on} ” and “ k_{off} ”), and concentrations of molecular species are tracked over time (ordinary differential equations (ODEs)) or time and space (partial differential equations (PDEs)). Depending on the timescale and level of model abstraction, the activity of enzymes (for GPCR systems, mostly GTPases, adenylyl cyclases, phosphodiesterases, kinases, and phosphatases) can be modeled using quasi-equilibrium Michaelis-Menten kinetics. Alternatively, enzyme-substrate binding and product formation kinetics can be explicitly included.

In just one example of the many systems relevant to neuroscience, several recent modeling efforts have used ODEs to investigate dopaminergic and glutamatergic signaling in the striatum and hippocampus. It has been shown that cross talk between GPCR receptor-activated networks and Ca^{2+} -activated networks (coming from the opening of NMDA receptors) modulates the strengthening and weakening of synapses (Kim et al. 2010; Fernandez et al. 2006; Nakano et al. 2010).

Compartmental models of biochemical signaling segregate relevant signaling domains into sub-cellular compartments, but do not explicitly consider the spatial movement of molecular species or the shape of a cell. Signaling molecules are assigned to compartments, and movement between compartments is typically defined such that the rate is dependent on species concentration. Within each compartment the system is assumed to be well mixed (fast diffusion), such that the model is still written in terms of ODEs.

Molecular diffusion and scaffolding are important processes that set up signaling sub-domains in the cell. They are of particular interest in neuroscience where cell shape is especially important; diffusion may not be assumed to be rapid due to molecular crowding, scaffolding proteins may act to increase local concentrations of signaling molecules, and spatial gradients of second messenger molecules (Ca^{2+} and cAMP in particular) are emergent properties of the system. When these processes are important considerations PDEs are employed to track concentrations of molecular species in both time and space. For some recent reviews of considerations in setting up compartmental and PDE models see Cowan et al. (2012), Neves and Iyengar (2009), and Blackwell et al. (2013). Examples in which PDEs have been employed to study neuronal GPCR function include: (1) a model of β_2 -adrenergic signaling in realistic neuronal volumes, where cell shape and negative biochemical regulation work together to form localized signaling domains (Neves et al. 2008), and (2) a study by Lenkei and colleagues showing that activation-dependent receptor endocytosis and endocytosis-dependent targeting of recycled receptors to the axon lead to

distinct differences in the axonal versus somatodendritic localization of CB1R cannabinoid and SSTR2 somatostatin receptors (Simon et al. 2013).

Stochastic models describe signaling events in terms of probabilities. In contrast to the deterministic models described above, stochastic equations are most useful when considering the spatial and/or temporal function of a small number of individual molecules. These considerations regularly arise in neuroscience due to the small volume and small number of molecules found in structures such as dendritic spines and spiny neurons and in the leading edge of axonal growth cones.

The challenge in employing stochastic models is that they are much more computationally intensive to solve and must be run multiple times in order to accurately calculate the probabilities of possible signaling outcomes. Readily available simulation environments to build and run stochastic simulations include MCell, Virtual Cell, Smoldyn, GENESIS and its associated packages (KinetiKit), and NeuroRD (Cowan et al. 2012; Vayttaden and Bhalla 2004; Oliveira et al. 2010; Andrews et al. 2010; Andrews 2012; Stiles and Bartol 2001; Kerr et al. 2008). See Blackwell (2013) for a recent review of these methods and simulation packages.

Despite the challenges and due to the increasing availability of computational power, reliable stochastic algorithms, and simulation packages, many researchers have used stochastic simulation to study GPCR mechanisms. These include studies to elucidate the complex interactions between ligands, receptors, and lipids at the membrane surface (Woolf and Linderman 2003; Brinkerhoff et al. 2004; Fallahi-Sichani and Linderman 2009), identify the role that RGS proteins may play in localizing and specifying GPCR signals (Zhong et al. 2003), and investigate the temporal and spatial effects of kinase activity downstream of GPCR signaling (Oliveira et al. 2012; Kim et al. 2013; Blackwell et al. 2013; Bhalla 2004a, b).

Other mathematical techniques provide relevant information. Data-driven modeling is used

for network reconstruction and analysis (Benedict and Lauffenburger 2013; Janes and Yaffe 2006). Sensitivity analysis identifies and classifies important model parameters (Zheng and Rundell 2006; Zi et al. 2008; Kinzer-Ursem and Linderman 2007). Molecular dynamics simulations provide insight into GPCR structure, oligomerization, and membrane interactions (Simpson et al. 2010; Selent and Kaczor 2011; Grossfield 2011; Filizola and Weinstein 2005). All these plus new methods to allow the incorporation of qualitative data from *in vivo* and *in vitro* experiments into quantitative models (Pargett and Umulis 2013) and model-based experiment design (recently reviewed by Chakrabarty et al. 2013) represent exciting directions for future work using computational models to elucidate complex phenomena in GPCR signaling.

There is little doubt that computational modeling will increasingly serve as a useful tool for understanding and elucidating mechanisms of GPCR and other complex biochemical networks. Indeed, simply examining the assumptions that one must make in order to mathematically describe a signaling network increases one's understanding of the system. Computational modeling can be applied to help interpret seemingly conflicting observations and offer new explanations of mechanisms underlying network behavior, provide insight into the role of distinct yet simultaneous signaling pathways in an observed behavior, identify potential new targets for therapeutic intervention, design maximally informative experiments, and much more.

Metabotropic Receptors Dynamics, Conductance Models

William Gibson

School of Mathematics and Statistics, University of Sydney, Sydney, NSW, Australia

Definition

A metabotropic receptor is a receptor, usually located on the surface of a cell, that when activated by the binding of transmitter leads to the activation of a secondary messenger system inside the cell. This in turn can induce a conformational change in ion channels in the cell membrane, thus modifying their conductance properties. In many cases, this secondary messenger system involves G-proteins, and thus the term “G-protein-coupled receptor” is often used instead of metabotropic receptor.

Detailed Description

A salient feature of metabotropic receptors is that they act on a much longer timescale (seconds to minutes) than directly gated (ionotropic) receptors, the latter typically acting on a timescale of a few milliseconds. Also, ionotropic receptors act only locally, whereas because of the secondary messenger system, metabotropic receptors can affect the behavior of ion channels in other parts of the cell. Another property is the amplification feature, in that one activated receptor molecule can activate hundreds to thousands of G-protein molecules and thus influence many ion channels in the cell. Examples of metabotropic receptors are muscarinic acetylcholine receptors, metabotropic glutamate receptors, GABA_B receptors, and beta-adrenergic receptors (Kandel et al. 1991). A number of these receptors either excite or inhibit neurons by either closing or opening K⁺ channels (Hille 1992).

A Simple Phenomenological Model

The basic signaling mechanism is shown in Fig. 1.

Let $c(t)$ be the concentration of transmitter at the receptor site. The receptor activation $a(t)$ can be described by a Michaelis-Menten-type formula:

$$p(t) = \frac{rc(t)}{k + c(t)},$$

where r is the receptor availability and k is a constant. Ignoring all details of the secondary messenger system, the activation $a(t)$ of the ion channel satisfies

$$\frac{da}{dt} = \frac{p(t)}{\tau_a} - \frac{a(t)}{\tau_i}.$$

The significant quantities here are the time constants τ_a and τ_i of activation and inactivation, respectively, and these can be chosen to give the desired time course (cf Postnova et al. 2010). The current through the ion channel is then

$$i(t) = ga(t)(V - E_R)$$

where g is the channel conductance, V is the membrane potential, and E_R is the reversal potential.

As a simple example, suppose transmitter is applied at a constant rate in the time interval $0 < t < t_0$. Then the above equations give a scaled activity $\bar{a}(t) = 1 - \exp(-t/\tau_i)$ for $t < t_0$ and $\bar{a}(t) = (\exp(t_0/\tau_i) - 1) \exp(-t/\tau_i)$ for $t > t_0$. By choosing a suitable value for τ_i , one can mimic the long time course of a metabotropic receptor.

A Model Incorporating G-Protein Coupling

Some metabotropic receptors may operate with a G-protein as the sole secondary messenger, as shown in Fig. 2 (Hille 1992).

Metabotropic Receptors Dynamics, Conductance Models, Fig. 1 Schematic diagram showing the basic mode of operation of a metabotropic receptor. The receptor is activated by the binding of a primary transmitter in the

extracellular space. This leads to the activation of a secondary messenger that diffuses inside the cell and binds to receptors on an ion channel, causing a change in the channel conductance

Metabotropic Receptors Dynamics, Conductance Models, Fig. 2 G-protein as the secondary messenger. Activation of the receptor causes the G-protein to bind to the intracellular domain of the receptor leading to GTP

replacing GDP in the G-protein, thus transforming it to the activated form G^* . This remains in the membrane and can interact directly with an ion channel

This process can be represented by the following equations (Destexhe et al. 1998; see also Destexhe et al. 1994).

T is transmitter, R is receptor, G is G-protein, C is the closed state, and O is the open state of the ion channel; the transition between these states is governed by the binding of activated G-protein molecules to n independent binding sites on this channel. Asterisks denote activated forms. The scheme also allows the receptors to go to a desensitized form, D . Kinetic equations can be

written for the concentration of substances in these reactions. These can be simplified by setting $d[R^*G^*]/dt = 0$ ("quasi-steady-state approximation") and assuming that G is present in excess, so $[G] \gg [G^*]$ ($[]$ denotes concentration). Also, R acts only as a catalyst, so $[R] + [R^*] + [D]$ is constant. This leads to the following equations (Destexhe et al. 1998).

$$\frac{d[R]}{dt} = K_1[T](1 - [R^*]) - K_2[R^*] + K_3[D]$$

$$\frac{d[D]}{dt} = K_4[R^*] - K_3[D]$$

$$\frac{d[G]}{dt} = K_5[R^*] - K_6[G^*],$$

where $[R^*]$ is the fraction of activated receptors, $[D]$ is the fraction of desensitized receptors, and

$[G^*]$ is the concentration of activated G-protein per receptor molecule. Assuming equilibrium between open and closed channels gives the fraction of open channels as $[G^*]^n/([G^*]^n + K_d)$, where K_d is the dissociation constant, and thus the current through a channel is

$$I = g \frac{[G^*]^n}{[G^*]^n + K_d} (V - E_R)$$

where g is the channel conductance, V is the membrane potential, and E_R the reversal potential. Destexhe et al. (1998) have applied the above method to the GABA_B receptor, where the ion channel is a K⁺ channel.

The above equations can be simplified by removing the desensitized state, D (Destexhe et al. 1998). Making the additional assumption that the activated receptor concentration changes slowly gives

$$[R^*] = \frac{[T]}{[T] + K_2/K_1}$$

It will be seen that this simplified version relates to the phenomenological model given above.

More Elaborate Models

In most cases the activated G-protein does not act directly on the ion channel, as in the above model, but sets off a cascade of events that involve substances such as adenylyl cyclase, cyclic AMP (cAMP), inositol 1,4,5-trisphosphate (IP₃), etc. (Kandel et al. 1991). One possible chain of events is shown in Fig. 3, where Ca²⁺ is released from internal stores.

This model has been developed in detail in Lemon et al. (2003). If it is assumed that there is

M

Metabotropic Receptors Dynamics, Conductance Models, Fig. 3 Release of Ca²⁺ from internal stores. The G-protein activation is as for Fig. 2, but rather than acting directly on an ion channel, G* binds to a site on phospholipase C-β (PLC) and this activated unit initiates an interaction with membrane-bound phosphatidylinositol 4,5-bisphosphate (PIP₂) leading to the hydrogenation of

PIP₂ and the production of IP₃. This diffuses into the cytosol where it opens IP₃-sensitive channels in the calcium store (endoplasmic reticulum, ER) allowing the release of Ca²⁺ into the cytosol. This Ca²⁺ can now have further effects, for example, increasing the current through Ca-dependent K⁺ channels (not shown)

no depletion of PIP_2 , then the production of IP_3 can be described by

$$\frac{d[\text{IP}_3]}{dt} = r_h^*[G^*] - k_{deg}[\text{IP}_3]$$

where r_h^* and k_{deg} are constants, and the release of Ca^{2+} by

$$\frac{d[\text{Ca}^{2+}]}{dt} = \beta(J_{\text{IP}_3} - J_{\text{pump}} + J_{\text{leak}})$$

where $[\text{Ca}^{2+}]$ is the cytosolic Ca^{2+} concentration; J_{IP_3} , J_{pump} , and J_{leak} are the rates of Ca^{2+} change due to release through IP_3 receptor channels on the ER, pump uptake into the ER and leaks from the ER, respectively; and β is a factor describing Ca^{2+} buffering. Expressions for these quantities can be found in Lemon et al. (2003). This formalism has been used in other applications, in particular, in modeling Ca^{2+} waves in arrays of astrocytes, where the slow action of metabotropic purinergic receptors is essential for obtaining the observed speeds of the waves (Bennett et al. 2005).

Definition

Bladder and bowel dysfunctions are frequently caused by neurological disease or injury such as spinal cord injury (SCI). With an annual incidence of 15–40 cases per million worldwide (Sekhon and Fehlings 2001), SCI results in neurogenic bladder or bowel dysfunction in a substantial percentage of cases (Levi et al. 1995). Surveys of quality-of-life measures in those with SCI show that the participants' highest priorities were restoration of bladder/bowel function, restoration of sexual function, restoration of sensation, and elimination of chronic pain (Anderson 2004). In an earlier study, subjects with SCI indicated that bowel and bladder dysfunctions have a significant effect on their lives, ranking neurogenic bladder and bowel dysfunction as one of their major life-limiting problems (Hanson and Franklin 1976). Electrical stimulation of the nervous system is an approach to restore bladder and bowel functions following neurological disease or injury.

Detailed Description

Normal Control of Bladder Function: Anatomy and Neurophysiology

The lower urinary tract (LUT), which includes the urinary bladder and urethra, serves two important roles: continence (the storage of urine in the bladder) and micturition (efficient voiding of urine from the bladder at an appropriate time). Under normal conditions, both of these functions are controlled by neural circuits in the spinal cord and brain. Neural signals encoding bladder control are transmitted to and from the bladder, urethra, and periurethral skeletal muscle via peripheral nerves that innervate the LUT.

The bladder and urethral sphincter are controlled in a reciprocal manner to accomplish continence and micturition. During storage, the smooth muscle of the bladder is relaxed and the urethral sphincter is contracted enabling low-pressure urine storage, while during voiding, the bladder muscle contracts and the urethral sphincter relaxes, allowing urine to leave the bladder (Beckel and Holstege 2011b).

The reflexes that facilitate urine storage and voiding are mediated through coordinated sympathetic, parasympathetic, and somatic neural activity. Sensory fibers in the hypogastric (sympathetic), pelvic (parasympathetic), and pudendal (somatic) nerves provide information from the bladder and urethra to the lumbar and sacral levels of the spinal cord. These sensory fibers enter the dorsal horn, projecting to local interneurons and projection neurons making ascending connections to the periaqueductal gray (PAG) and pontine micturition center (PMC) (Benarroch 2010). Descending modulation from these areas innervates the sacral parasympathetic nucleus (SPN) and somatic Onuf's nucleus. Originating from the SPN, pelvic nerve efferents are responsible for contraction of the bladder. The output of Onuf's nucleus, the pudendal nerve, controls the contraction or relaxation of the external urethral sphincter (EUS) and provides sensory input about flow in the urethra to the sacral spinal cord, which can act as important feedback during micturition (Shafik et al. 2003).

During bladder filling, the pelvic afferents carry signals from stretch receptors in the bladder wall and signal bladder distention to the spinal cord (Fowler et al. 2008). To maintain storage, the sympathetic pathway is activated and tonic output to Onuf's nucleus is increased (Benarroch 2010), which results in relaxation of the bladder and contraction of the EUS, respectively.

The higher level control of micturition is complex, involves multiple brain areas, and relies on ascending information from spinal circuits and sensory peripheral nerve inputs. The PMC plays a critical role and may act as the efferent switch between storage and voiding phases, although higher brain areas provide inputs which determine when it is on or off (Beckel and Holstege 2011a). When the PMC is excited, descending pathways are activated, resulting in urethral relaxation and an increase in SPN activity, which, via the pelvic nerve, causes a contraction of the bladder (Fowler et al. 2008). The synchronized activation of the SPN and the inhibition of the somatic Onuf's nucleus induce a coordinated contraction of the bladder and relaxation of the EUS, which results in efficient bladder emptying (Kinder et al. 1995).

Disorders Affecting Bladder and Bowel Function

Neurological diseases and injuries such as SCI or trauma, multiple sclerosis, transverse myelitis, spina bifida, tumors of the brain or spinal cord, dementia, and pelvic surgical injuries can disturb normal bladder or bowel function. Bladder dysfunction can cause urinary incontinence, the involuntary leakage of urine; urinary retention, the lack of the ability to urinate; and detrusor-sphincter dyssynergia (DSD), bladder contractions concurrent with an involuntary contraction of the urethral musculature. The location and severity of the injury affect the degree of dysfunction, which could include interrupting communication between the sacral spinal cord and pontine micturition centers or directly damaging part of the sacral spinal circuits that control detrusor and sphincter functions (Benevento and Sipski 2002).

Additionally, bladder conditions and dysfunction may change over the course of an injury and recovery as a result of neuronal plasticity, making bladder management a persistent challenge.

Treatments of Bladder Dysfunction

Treatment of bladder dysfunction commonly includes pharmacological intervention and urethral catheterization, although these may be accompanied by drug side effects and frequent urinary tract infections. In cases of bladder dysfunction such as DSD, the goal of treatment is to provide bladder emptying while maintaining low bladder pressures during both storage and voiding. Anticholinergic medications, e.g., oxybutynin, may be used to suppress detrusor contractions and combined with intermittent catheterization to empty the bladder. Blockers of alpha-adrenergic receptors, e.g., tamsulosin, can be prescribed to reduce internal urethral sphincter or bladder neck resistance in males, and other types of medications, e.g., baclofen, may be used to decrease muscle spasticity in the pelvic floor (Burns et al. 2001).

More aggressive interventions are often necessary if these pharmacological treatments fail to restore continence or allow for micturition. In some cases, surgical interventions, such as a transurethral sphincterotomy or the placement of a urethral stent, may be used to prevent DSD or decrease outlet resistance. In cases of detrusor hyperreflexia, where the bladder is hyperexcitable, treatment with intravesical capsaicin or botulinum A toxin may be performed to paralyze the bladder and prevent incontinence.

Functional electrical stimulation with the goal of emptying the bladder at a desired time to produce low residual volumes has been increasingly used when more conservative treatments are unsuccessful or intolerable. Many different stimulation locations have been investigated for the application of electrical stimulation to restore functional bladder control, with varying degrees of success (Fig. 1).

There are five locations where electrical stimulation electrodes could be placed in an attempt to

control bladder function in SCI: the bladder, skin, peripheral nerve, sacral roots, and spinal cord (Gaunt and Prochazka 2006). There has been limited clinical success with direct bladder wall stimulation due to problems with concomitant sphincter activation, pain, or device failure (Bradley et al. 1963; Hald et al. 1967; Stenberg et al. 1967). Spinal cord stimulation for bladder control has not been well received either, as it does not provide benefits over sacral root stimulation, it is very invasive, and it had high complication rates (Nashold et al. 1981). Transcutaneous electrical stimulation for bladder control, e.g., dorsal penile nerve surface stimulation to inhibit bladder activity, targets peripheral nerves through a less invasive manner. However, skin stimulation is less common than more invasive approaches to stimulate peripheral nerves due to discomfort in persons with incomplete SCI (Previnaire et al. 1998) and practical challenges of chronic stimulation with surface electrodes. Peripheral nerve and sacral root stimulations have proved to be the leading candidates for effective restoration of bladder function with electrical stimulation.

Neuromodulation with sacral anterior root stimulation, Finetech-Brindley SARS, can produce efficient voiding in those with SCI (Brindley et al. 1982). However, implantation requires a concomitant surgical transection of the sacral dorsal roots (posterior rhizotomy), which limits detrusor-sphincter dyssynergia but irreversibly eliminates reflex erection, reflex micturition, and any remaining sensation. Sacral nerve stimulation with InterStim[®] (Medtronic Inc., Minneapolis, MN, USA) has been shown to treat effectively overactive bladder by reducing bladder hyperreflexia and increasing cystometric capacity (Vodusek et al. 1986; Ishigooka et al. 1998), although it has not been effective at restoring bladder function in those with SCI, as it rarely produces on-demand voiding (Chartier-Kastler et al. 2001; De Ridder et al. 2007). Success with InterStim[®] is highly dependent on etiology, and while it has been generally effective for overactive bladder, it has not been as effective in producing efficient voiding in a majority of patients with bladder retention.

Methodologies for the Restoration of Bladder and Bowel Functions, Fig. 1 Neuroanatomy of the lower urinary tract and locations targeted for restoration of bladder control using electrical stimulation. Afferents from the bladder and pelvic floor enter the spinal cord, where they send information to local interneurons and ascending fibers (AF). Descending modulation (DM) relays signals from the pontine micturition center that control the outputs of the sacral parasympathetic nucleus (SPN) and Onuf's nucleus

(ON). Locations where electrical stimulation has been tested for restoration of bladder function are shown, including (A) bladder, (B) spinal cord, (C) skin, (D) sacral anterior roots, (E) sacral nerve, and (F) pudendal nerve. M

Peripheral nerves provide multiple locations for the application of electrical stimulation for control of bladder function. Pelvic nerve stimulation was shown to produce bladder contractions in dogs but also resulted in undesirable co-activation of urethral sphincters (Holmquist and Olin 1968). Tibial and pudendal nerve stimulations are currently being investigated and may be effective targets for control of bladder function. Uniquely, electrical stimulation of the pudendal nerve is capable of producing both excitation of the bladder and voiding, in addition to bladder inhibition and continence, in cats (Boggs et al. 2006; Tai et al. 2007) and rats (Peng et al. 2008). Importantly, these inhibitory and excitatory reflexes have also been demonstrated in persons with SCI (Kirkham et al. 2001; Gustafson et al. 2004; Yoo et al. 2007).

Treatments of Bowel Dysfunction

The goals of managing bowel dysfunction include continence of stool, willful and independent defecation, and the prevention of additional gastrointestinal complications (Stiens et al. 1997). Bowel programs, including individualized treatment plans of scheduled bowel evacuations and careful dietary planning, are often used to prevent incontinence and achieve effective colonic evacuation (Stiens et al. 1997). In cases of areflexic bowel, bowel programs must be performed more frequently and manual evacuation may be required. Medications used to manage neurogenic bowel dysfunction include stool softeners, laxatives, prokinetic agents, and fiber. Surgical treatments of bowel dysfunction include antegrade colonic enema with an appendicostomy or

colostomy formation (Glickman and Kamm 1996). Sacral anterior root stimulation (SARS), which has been used to treat neurogenic bladder dysfunction, may also improve bowel function. SARS significantly increased bowel movement frequency, reduced the number of methods needed to evacuate bowel, and reduced constipation in a study of patients with SCI (Vallès et al. 2009).

Definition

Invasive techniques to interface with the spinal cord are often selected for patients suffering pain conditions that are refractory to conventional medical management. These spinal interfaces for the treatment of pain can include epidural electrical stimulation and intrathecal drug delivery.

Detailed Description

Introduction

A significant number of patients suffering chronic pain do not respond well to standard pharmacological therapies. For these patients, more invasive therapies are often considered. One standard therapy is electrical stimulation of the spinal cord with electrode arrays implanted in the epidural space dorsal to the spinal cord. Another common treatment option is the delivery of analgesics by insertion of a catheter system inside the intrathecal space of the spine. Due to the invasive nature of these therapies, they are typically selected as a last resort for pain management.

Spinal Cord Stimulation

Spinal cord stimulation (SCS) is a pain management therapy for patients suffering from specific types of chronic pain conditions that are refractory to conventional medical management (CMM) (e.g., pharmacological treatments). SCS was first tested in patients in 1967 and is now considered a routine surgical option (Shealy et al. 1967). It is estimated that approximately 15,000 SCS systems are implanted yearly in the USA alone at a cost of more than one billion US dollars (Linderroth and Meyerson 2002). Although SCS has a high initial cost, studies have shown its long-term potential cost-effectiveness relative to other treatment options (Linderroth and Meyerson 2009; North and Linderroth 2010).

SCS is typically considered for neuropathic limb pain that is refractory to CMM, including conditions such as failed back surgery syndrome (FBSS) and chronic regional pain syndrome (CRPS). SCS has also been indicated in visceral abdominal pain as well as ischemic pain resulting from peripheral vascular disease or stable coronary insufficiency (Linderroth and Meyerson 2009). Studies have shown a higher rate of success and improved patient quality of life with SCS in combination with CMM relative to CMM alone (Linderroth and Meyerson 2009). SCS-induced pain relief of 50% or more is typically considered a satisfactory outcome.

Methodologies for the Treatment of Pain,

Fig. 1 Possible mechanisms of spinal cord stimulation (SCS). In SCS, an electrode array is inserted into the epidural space dorsal to the spinal cord. Electrical pulses are applied through the electrode(s) in an attempt to excite the large-diameter myelinated fibers in the dorsal column (DC) resulting in both orthodromic and antidromic action potential propagation. According to the gate-control theory, antidromic propagation is believed to activate inhibitory interneurons that attenuate the transmission of pain signals to the brain by projection neurons (i.e., close the “gate”). Orthodromic activation of the DC fibers can produce activation of supraspinal areas and possible modulation of descending inputs to the spinal cord. (Figure reproduced from Smits et al. (2013) with permission from Wiley)

SCS involves implantation of a multielectrode array in the epidural space dorsal to the spinal cord a few levels above the affected spinal segments (Fig. 1). Electrical pulses are typically applied at a moderate frequency (e.g., 50–60 Hz) with the goal of exciting the large-diameter ($A\beta$) sensory afferents in the dorsal columns (DC) to create paresthesias (i.e., tingling) over the painful areas. According to the gate-control theory, some of the $A\beta$ fibers have collaterals that project to the affected spinal levels. SCS results in antidromic

activation of the $A\beta$ fibers that in turn (via their collaterals) lead to inhibition of nociceptive-specific or wide dynamic range projection neurons in the dorsal horn. In neuropathic pain conditions, excessive nociceptive inputs are believed to produce hyperexcitability in these projection neurons (i.e., central sensitization). One of the possible mechanisms underlying the effects of SCS is antidromic activation of $A\beta$ fibers, inhibiting output from these projection neurons largely through the activation of inhibitory

interneurons that help close the “gate” and prevent the transmission of pain signals to the brain (Guan 2012).

Although the effects of SCS may be mediated by spinal or segmental mechanisms as described above, multiple supraspinal mechanisms have also been implicated in SCS-induced analgesia. Orthodromic activation of DC fibers during SCS is relayed through the DC nuclei and transmitted from the brainstem to the sensory thalamus and to the cortex. SCS has also been shown to modulate evoked potentials in both the thalamus and cortex (Linderth and Meyerson 2002). Descending pathways have also been shown to play a role in the development and maintenance of neuropathic pain, and experimental evidence suggests SCS may lead to activation of descending inputs to the spinal cord (Guan 2012). Although SCS has been implemented clinically for several decades, the therapeutic mechanisms of SCS are still poorly understood. Several references are available discussing its potential mechanisms of action (Linderth and Meyerson 2002; Linderth et al. 2009; North and Linderth 2010; Guan 2012).

Two types of electrode arrays are common in SCS: cylindrical or paddle leads (Fig. 2). Cylindrical leads have multiple electrodes (e.g., 4–8) on the distal end and can be implanted in the epidural space with minimally invasive percutaneous techniques. The lead location is guided with fluoroscopy and intraoperative stimulation is often used to determine the final lead location in which stimulation produces maximal paresthesia coverage over the painful area. The most common complication of SCS with cylindrical electrodes is lead migration that results in a loss of therapeutic efficacy (de Oliveira and Machado 2012).

Paddle leads are a second option that can be considered for SCS (Sears et al. 2011). Paddle leads can often be directly anchored to spinal elements and thus have a lower risk of migration relative to cylindrical leads. The geometry of paddle leads improves stimulation efficiency (North et al. 2002), and modern paddle leads typically have a large number of electrodes (e.g., 8–16) that increase programming options in an attempt to

Methodologies for the Treatment of Pain, Fig. 2 Electrode arrays for spinal cord stimulation (SCS). (a) An example of an eight-contact cylindrical electrode array that can be implanted in the epidural space with minimally invasive percutaneous techniques using a needle. (b) Two different geometries of paddle electrodes used for SCS. These electrode arrays must be surgically implanted by removing a portion of the vertebral bone called the lamina. The electrode on the left has four contacts, while the electrode on the right has two columns of staggered electrodes (16 electrodes total)

improve therapeutic outcomes. The main drawback of paddle leads is that implantation requires a laminectomy or laminotomy, which is an open surgery with removal of a small portion of the lamina in order to pass the paddle lead.

Before an SCS system is permanently implanted, a short trial period (e.g., 5–10 days) with the electrode wires externalized is often utilized to assess the efficacy of stimulation. If the therapy is deemed effective (e.g., pain relief $\geq 50\%$), the patient may then undergo a second procedure for implantation of a fully internal (implantable) system with percutaneous or paddle leads (Fig. 3a). Detailed descriptions of the equipment, surgical procedures, and complications of SCS are available (Linderth and Meyerson 2009; North and Linderth 2010; Rauck et al. 2012; Feler 2012).

pulse generator. (b) Example of an implantable drug delivery pump and catheter system (Images courtesy of Medtronic, Inc., Minneapolis, MN)

Infusional Therapies

Intrathecal infusion can be accomplished via externalized catheters or implanted systems (Slavin 2002). Externalized infusion is typically utilized for acute pain management of in-hospital patients, including postsurgical pain management. Externalized infusion can also be utilized to test the effects and side effects of intrathecal infusion of opioid and non-opioid medications to inform the patient's candidacy for a fully implanted system (Levy 2002; Osenbach 2010). The implantable medical devices for intrathecal infusion consist of a combination of an implantable pump and catheter system (Fig. 3b) (Slavin 2002). The pumps can be programmable or nonprogrammable. The main advantage of programmable pumps is that the daily dose of medications can be adjusted via telemetry, without changing the concentration of the medication. Nonprogrammable pumps infuse only at one set rate, and to change the daily dose, it is necessary to drain the medication from the pump and reload it with a new concentration. The pumps are typically implanted in the abdominal area, but other surgical sites are also possible.

The surgical procedure for implantation of these devices can be explained in three steps (Slavin 2002; Osenbach 2010). The first step is insertion of the catheter, typically through a lumbar tap with a Tuohy needle. The catheter is typically advanced to the thoracolumbar transition under fluoroscopy. The second step is to tunnel the intrathecal catheter or a second, more resistant, catheter from the low back to the abdominal area. The third step is to implant the pump in a subcutaneous abdominal pocket and connect to the catheter system.

While intrathecal infusion remains a viable and commonly utilized alternative for pain management, its use has declined significantly over the past decades mostly due to concerns related to limited long-term efficacy, side effects, and complications. Intrathecal pumps serve as an alternative route for delivery of pharmacological agents that allows for maximal analgesia with lower effective doses and subsequent reduced side effects. However, chronic intrathecal infusion can be associated with cognitive and behavioral changes as well as other complications associated with chronic use of opioid medications (Osenbach 2010; de Oliveira and Machado 2012). New, non-opioid, medications are currently being evaluated for intrathecal infusion and may significantly

boost the future utilization of these devices (Reig et al. 2009). As for all surgical procedures, there are possible complications associated with implantable intrathecal systems (Slavin 2002; Osenbach 2010; de Oliveira and Machado 2012). Some of the most common complications are related to the catheters, which can migrate, plug, kink, or break. These complications can be evaluated via imaging studies and surgical revision is required to correct them. Although malfunction of the pump mechanisms have been reported, they are uncommon. In recent years, formation of granulomas in the tip of the intrathecal catheters has been reported as a cause of malfunction and neurological deficits. Unlike patients with spinal cord stimulation, patients with intrathecal pumps can have magnetic resonance imaging of the body and imaging studies are ordered when catheter tip granuloma is suspected. Future improvements of this technology for pain management depend not only on device miniaturization (pumps remain much larger than neurostimulators) but also combined development of new drugs and delivery systems.

Definition

The increasing interest in and use of bioelectronic devices, also known as electroceuticals, as a medical therapeutic is necessitating the use of optimized stimulus waveforms in order to minimize adverse effects and maximize battery life. This entry examines how these optimized stimulus waveforms can be found including both traditional model-dependent approaches and some of the newer model-independent techniques.

Detailed Definition

Recent advances in a variety of disciplines, ranging from electrode technology to anatomical and functional mapping of the nervous system to digital waveform generators, have ushered in a new age of electrical stimulation, or electroceutical, therapies. While the use of electrical shocks as a therapeutic modality is not new, the ability to precisely target fine structures in brain and nerves is allowing for an unprecedented level of control over the nervous system. These technologies are being explored and studied to treat medical conditions including Parkinsonian tremors, epilepsy, inflammatory and autoimmune disorders, and heart failure (Majid 2017).

One of the challenges associated with the development of any new therapy is determining the optimal dosing protocol. Historically, dosing

of current stimulation was limited to the strength and the duration of stimulation. Modern digital waveform generators can construct arbitrary waveforms on the fly, opening up a completely new world of potential waveform shapes. Even though this technology exists today, the majority of electroceutical devices on the market still use standard waveform shapes, rectangular or sinusoidal, allowing clinicians only a limited number of parameters to adjust.

It is important to note that there are many ways to define optimality. Studies have shown that excessive electrical stimulation can cause damage to tissue (Merrill et al. 2005), and, thus, it is important to minimize the amount of stimulation so as to prevent such damage. Yet, even with this definition of optimality, there are different metrics by which to measure “excessive” stimulation, and most of this is application-dependent. In some situations, one may want to minimize total charge delivered in order to minimize tissue damage due to inappropriate electrical gradients imposed on the cells or charge deposition within cellular structures, while in other scenarios, one may want to minimize time to effect of the stimulus, sacrificing charge optimization for more expedient effects, for instance, in cardioversion. For the purposes of the rest of this entry, energy efficiency will be used as the default primary optimization objective, though most of the methods discussed can be easily adapted for other objectives as well.

Given a particular optimization metric, the challenge is how to find these optimal stimulus waveform shapes. A handful of studies exist that have questioned the use of the traditional rectangular waveform shape using a set of alternative shapes including linear ramps, exponential ramps, and Gaussian and sinusoidal waveforms. Using a predefined waveform shape is easier because the number of tunable parameters becomes manageable. Both computational and experimental studies have shown that non-rectangular waveforms are actually more optimal. The problem is that searching across arbitrary waveform shapes is nearly impossible due to the infinite number of possibilities that exist. All search methods can be broken down into roughly two categories: model-dependent methods that leverage the prior

knowledge of the system, usually in the form of mathematical equations, and model-independent methods, which treat the system like a black box.

Model-Dependent Approaches

The challenge with using predetermined alternative waveforms is that the optimized waveform found is biased to the constrained solution space. Model-dependent approaches leverage existing knowledge of a system, in the form of a mathematical model, in order to calculate optimality.

The use of calculus of variations (Gelfand et al. 2000) as a tool to solve for optimal stimulus waveforms was utilized first by Offner (1946) and later by Jezernik and Morari (2005), as well as Forger et al. (Forger and Paydarfar 2004; Forger et al. 2011). Using relatively simple neuronal models, they were able to analytically solve for a system of equations defining optimality. Mathematically, the biological system is represented as

$$\dot{x} = f[x(t), u(t)], \quad (1)$$

where $x(t)$ describes an m -dimensional system and $u(t)$ describes an n -dimensional external stimulus acting on the system. The goal of this approach is to find an optimal $u^*(t)$ such that a performance metric, $J[u]$, is minimized. The performance metric can be defined as

$$J[u] = \int L[x(t), u(t), t] dt, \quad (2)$$

where $L[x(t), u(t), t]$ represents the performance metric. In the case of optimizing energetics, most studies use the L^2 -norm of the stimulus:

$$L[x(t), u(t), t] = u^2. \quad (3)$$

Once the problem is defined, calculus of variations or Pontryagin's Maximum Principle (Pontryagin et al. 1962) is used to develop a set of additional equations defining the optimal function. Whereas traditional calculus often seeks to find the maxima or minima of functions, setting the derivative to zero, calculus of variations seeks to find the maxima or minima of functionals,

functions of functions. This is done by setting the functional derivative to zero. Given Eqs. 1 and 2, the fundamental lemma of calculus of variations states that

$$\frac{\partial L}{\partial f} - \frac{d}{dx} \frac{\partial L}{\partial f'} = 0. \quad (4)$$

This is known as the Euler-Lagrange equation. In the case of both Offner's and Jezernik's work, the computational models were simple enough that a closed form solution could be generated using variational approaches. In Forger et al., a closed form solution was not possible due to the complexity of the system of equations being solved, and so the shooting method was used to numerically compute the optimal waveform. In order to accomplish this, Forger et al. used Lagrange multipliers to combine the equations governing the system with the optimization metrics to form a new $J[u]$:

$$J[u] = \int L[x(t), u(t), t] + \lambda (f[x(t), u(t)] - \dot{x}) dt, \quad (5)$$

Applying the Euler-Lagrange equations results in a set of new differential equations on top of the original differential equations governing the system. These new differential equations govern the Lagrange multipliers, and using numerical methods like the shooting method or Newton's Method, a numerical approximation can be constructed. A full derivation and explanation can be found in Forger and Paydarfar's work (Forger and Paydarfar 2004). This class of techniques that use Lagrange multipliers to create an intermediate set of equations defining optimality is known as indirect methods. While they produce equations that define optimality, solving for the numerical approximation is a difficult task as the initial conditions for the lambda values must be guessed. Guessing these values incorrectly can lead the numerical approximation to diverge toward infinity.

Because of the challenges, a set of direct methods has also been formulated, built also on

calculus of variations. Instead of first computing a new set of constraining equations that define optimality using indirect methods, direct methods iteratively progress toward more optimal solutions from a starting seed using calculated gradients. By not adding a new set of constraining equations to the system, these methods allow for a larger region of convergence from the initial estimate. Both Betts and Rao provide useful reviews on these numerical methods for optimal control (Betts 1998; Rao 2009). Through such direct methods, models like the Hodgkin-Huxley can be solved to compute an optimal stimulus waveform to elicit an action potential as seen in Fig. 1 (Chang and Paydarfar 2014). It is interesting to note that the optimal stimulus waveform as computed through calculus of variations is not rectangular and in fact outperforms the best rectangular pulse waveform.

It is important to note that even with direct methods, as the systems become more complex and the number of equations grows, calculating even first-order gradients becomes difficult. Solving these complex systems of equations becomes nearly intractable. Some researchers have sought to simplify the system of equations using phase reduction techniques, representing oscillatory systems by their phases (Moehlis et al. 2006; Danzl et al. 2010; Nabi and Moehlis 2012). By simplifying these systems to a more

manageable and analytically tractable problem, insights can be gained, and more useful design-based control solutions can be computed (Monga et al. 2019). Monga et al. provide an excellent in-depth tutorial on phase reduction and phase-based optimal control. The challenge with these methods are that they still require (1) a mathematical model of the oscillatory behavior of the system and (2) they collapse a complex mathematical model to a single state, the phase, potentially losing out on other key insights gained from the other state variables. Furthermore, the use of models will always require a trade-off between the complexity of the mathematical framework and its accuracy. At the end of the day, no model is as accurate as the actual biological system.

Model-Independent Approaches

In all of the above approaches, a mathematical model is required to begin applying calculus of variations or other optimal control methods. In some cases, these models are nonexistent, or they are very large and complicated and thus not amenable to phase reduction or pseudospectral techniques. A class of methods born out from computer science called stochastic search approaches were developed to find optimality in systems where a model does not exist, so called “black box” systems.

Methods for Optimizing Stimulus Waveforms for Electroceutical Control,

Fig. 1 System response (top) to optimized stimuli (bottom). Stimulus determined by calculus of variation (orange) outperforms the optimal rectangular stimulus (blue)

One of these stochastic approaches, genetic algorithms, constructs a “population” of solutions, represented as vectors or “chromosomes.” Genetic algorithms, inspired from biological evolution, manipulate these chromosomes through an iterative process of mutation, cross-over, and selection. For an overview of this process, we refer readers to Forrest’s work (Forrest 1993). A few different research groups have sought to use genetic algorithms to find optimal stimulus parameters and shapes including Wongsarnpigoon and Grill who optimized action potential stimulation in a peripheral mammalian axon (Wongsarnpigoon and Grill 2010), Yip et al. who studied electrical stimulation of the cochlear nerve (Yip et al. 2017), and Feng et al. who examined suppression of Parkinsonian behavior in a computational subthalamopallidal model (Feng et al. 2007).

In each of these cases, the number of stimuli necessary to test was very large due to both the size of each population and the number of generations required for convergence. This large iteration count is fairly common in stochastic search approaches. Bellman introduced the phrase, “curse of dimensionality” in 1957 (Bellman 1957). He noted that the addition of extra dimensions in a search space resulted in an exponential increase in the solution space. In most of the applications examining the optimization of stimulus shape, the stimulus is represented as a vector containing the stimulus intensities at a specific resolution. Thus, a 30-ms stimulus sampled at 0.1-ms resolution would be contained with a 300-unit vector. For every increase in either resolution or stimulus duration, the search space becomes exponentially large, resulting in extremely large iteration numbers.

In order to address this “curse of dimensionality,” Chang and Paydarfar leveraged the idea of focusing on extrema features (Chang and Paydarfar 2018a). The use of extrema features has been prevalent in signal analysis and pattern recognition, acknowledging the idea that the extrema features often hold the most information about the signal itself. Instead of treating the stimulus intensity at every time step as a unique

dimension, focusing solely on the extrema reduced the dimensionality of the problem and allowed for more efficient, model-independent searching. Chang and Paydarfar tested this concept using a simpler approach called stochastic hill climbing. In this method, a randomly generated stimulus is used as an initial seed. Neighboring solutions are examined around that initial seed, and the best is chosen to be the initial seed of the next generation. This iterative process continues until the program converges. Normally neighboring solutions are determined by adding noise to each of the stimulus intensities at every time point. By focusing on extrema, noise was added to the amplitude of the extrema and the intervals between the extrema. The intermediate signal was reconstructed using a linear translation of the original stimulus with new extrema as seen in Fig. 2.

An outline of the algorithm is as follows:

1. Choose an initial randomly generated stimulus.
2. Identify the extrema of the stimulus.
3. Add noise to the amplitudes of each of the extrema while multiplying the interval between extremas by a random value.
4. Calculate the performance metric of the resulting stimulus, penalizing the metric if the stimulus does not successfully cause the desired transition (e.g., an action potential or a state switch).
5. Repeat steps 2–4 ten times to produce ten neighboring solutions based on the initial stimulus.
6. Identify the stimulus that performs the best.
7. Repeat steps 2–6 for a predetermined number of iterations or until the performance metric has converged, using the best stimulus found thus far as the initial stimulus for the next iteration.

It is important to note that by chance, extrema may move in such a way that they are no longer extrema in the next iteration. As seen in Fig. 2, extrema E_2 and E_3 move in such a way that in the next iteration they would no longer be considered extrema. This phenomenon also helps to reduce the dimensionality of the problem as the

Methods for Optimizing Stimulus Waveforms for Electroceutical Control, Fig. 2 Use of extrema features to reduce dimensionality in optimizing stimulus waveform shapes

Methods for Optimizing Stimulus Waveforms for Electroceutical Control, Fig. 3 Optimal stimulus as computed by extrema-driven stochastic search (blue) matches very closely with calculus of variations (orange)

search process continues. As more and more of the unnecessary extrema are weeded out, the search becomes more efficient. As can be seen in Fig. 3, the result from this process matches very closely to results computed using calculus of variations.

Future Directions

As one can see from this review, there are still plenty of opportunities to further refine these methods to finding optimal control in electroceutical systems. Chang and Paydarfar provide a

more in-depth review of these techniques (Chang and Paydarfar 2018b). As the clinical applications continue to grow and more researchers explore the potential of electrical stimulation as a medical therapy, the need to find ways to optimize these waveforms becomes ever more important. Moreover, the use of these methods may help reveal unique mechanisms in our understanding of neurological processes. Clay et al. demonstrated this with their analysis of the optimal stimulus waveform for single neurons modeled by the Hodgkin-Huxley equations (Clay et al. 2012). The optimal stimulus waveform for the Hodgkin-Huxley model is composed of a relatively long and shallow hyperpolarizing phase followed by a rapid depolarizing component. By analyzing this optimal stimulus waveform and the state variable responses, they recognized that the hyperpolarizing component was removing sodium channel inactivation, allowing the depolarizing component to fire the neuron more efficiently. Their results showed how optimized stimulus waveforms relate to the ionic dynamics and can be used to gain insight into how nature structures energy efficiency in neural excitation.

Metric Space Analysis of Neural Information Flow

Conor Houghton

Department of Computer Science, University of Bristol, Bristol, UK

Definition

In the metric-space approach to spike train analysis, spike trains are regarded as points in a metric space, that is, a space with a distance defined between any pair of points.

Detailed Description

Spike Train Metrics

The Victor-Purpura metric (Victor and Purpura 1996) is one common way to define a metric distance between spike trains. The Victor-Purpura metric considers a fictional total cost for transforming one spike train into another using three basic operations: spike insertion, spike deletion, and spike movement. Each basic operation is given an individual cost, one for inserting or deleting a spike and $q|\delta t|$ for moving a spike a temporal distance δt . The cost-per-time, q , is a parameter, with the timescale $2/q$ thought of as corresponding to the temporal precision of spike times in the metric. The distance between the two spike trains is then defined as the cost of the cheapest transformation of one to the other. In other words, the distance between spike trains x and y is given by

$$d(x, y) = \min_{\gamma \in \Gamma} c(\gamma) \quad (1)$$

where γ is a sequence of basic operations transforming x to y , Γ is the set of all such sequences, and $c(\gamma)$ is the cost of γ , that is, the sum of the individual costs of the basic operations that make up γ . This is not the only spike-train metric: there is also the van Rossum metric (van Rossum 2001) which is part of a kernelization approach to spike trains (Paiva et al. 2009), and there are more recent metrics like the synapse metric (Houghton 2009) and the ISI-distance (Kreuz et al. 2007). These are reviewed and compared in, for example, Victor (2005), Houghton and Victor (2012), and Houghton and Kreuz (2013). There are also multi-neuron metrics (Aronov et al. 2003; Houghton and Sen 2008), which allow metric-based methods to be applied to multiunit data.

In a metric-space approach to analyzing a collection of spike trains, the data is reduced from a set of complicated objects, spike trains, to a much simpler object, the matrix of distances between the trains. When applied to neural information, the information contained in this matrix is used to estimate information theory quantities for the corresponding spike train data; typically the

quantity of interest is the mutual information between a sensory stimuli and a spiking response. Of course, this reduction of the data to the distance matrix is a simplification and it is likely that the metric will not be sensitive to all the information-carry features of the spike trains. This means that the information contained in the distance matrix will underestimate the true mutual information. However, it is hoped that metric-based methods will be less prone to bias on small data sets than traditional approaches like the direct method described in Strong et al. (1998). There are sophisticated bias-reduction techniques developed for the direct method (Nemenman et al. 2007; Paninski 2003; Panzeri et al. 2007), and it is unclear as yet whether bias is a substantial enough problem to warrant consideration of metric-based methods.

The Transmitted Information

The transmitted information applies to situations when the spiking data represents multi-trial responses to a set of distinct data. In this case, the spike trains can be clustered by stimulus and the transmitted information estimates the mutual information between this “true clustering” and metric-based clustering. The transmitted information is written in terms of a matching or confusion matrix N . If the stimuli are labeled by $s = 1, \dots, S$ and the responses are grouped into clusters labeled $c = 1, \dots, C$, then N is an $S \times C$ matrix whose element n_{sc} is the number of responses to stimulus s placed in cluster c . This means that the probability that a response to stimulus s is placed in cluster c is estimated as $p(s, c) \approx n_{sc}/n$, where $n = \sum_{s=1}^S \sum_{c=1}^C n_{sc}$ is the total number of responses. The transmitted information, h , measured in nats, is derived by substituting this into the usual definition of the mutual information:

$$h = \frac{1}{n} \left(\sum_{s=1}^S \sum_{c=1}^C n_{sc} \ln n_{sc} - \sum_{s=1}^S n_s \ln n_s - \sum_{c=1}^C n_c \ln n_c - n \ln n \right) \quad (2)$$

where, in an abuse of notation, $n_c = \sum_{s=1}^S n_{sc}$ and $n_s = \sum_{c=1}^C n_{sc}$ denote the row and column sums.

Although the transmitted information is straightforward to calculate once the data have been clustered, it does rely on a clustering algorithm as well as a metric, and, in practice, the transmitted information will substantially underestimate the mutual information. In fact, the confusion matrix is often calculated by clustering the data by stimulus, removing individual data points one-by-one and deciding which cluster the test point is closest to. This is not an unsupervised clustering, and this transmitted information does not measure the actual mutual information, it is used as a comparative quantity, for example, it was originally introduced in Victor and Purpura (1996) as a way to determine the optimal value of the parameter q in the Victor-Purpura metric.

A Kozachenko-Leonenko Estimate

In Kraskov et al. (2004) the mutual information is estimated using the Kozachenko-Leonenko k -nearest-neighbors estimator (Kozachenko and Leonenko 1987). This approach is developed in the case where the stimuli are also points in a metric space, rather than points in a discrete case, as was considered for the transmitted information above. The Kozachenko-Leonenko estimator requires the calculation of the rate of change of the probability of finding a data point as a sphere increases; in Kraskov et al. (2004) this rate of change is calculated using the coordinate-based measure and it is assumed the stimulus and response spaces both have a well-defined dimension. These assumptions do not hold in the case of the space of spike trains. However, different k s are used in the stimulus and response spaces. This is done to allow biases in the entropies $H(R)$, $H(S)$, and $H(R, S)$ to cancel, but, fortuitously, this is done in such a way that all the terms that depend on the dimension of the two spaces, or on the volumes of spheres in those spaces, also cancel. This leads to a formula which can be applied to spike trains; in fact, it is possible to derive a Kozachenko-Leonenko estimator for the mutual information directly for metric spaces (Houghton 2015).

Let R be the random variable corresponding to the spiking response and S the random variable corresponding to the stimulus. S is now a

continuous random variable and could correspond to a continuous stimulus, such as the position of a foraging rat, or to another spike train. It is assumed that there are metrics on both spaces; this in turn induces a metric on the space of stimulus-response pairs:

$$d[(s_1, r_1), (s_2, r_2)] = \max [d(s_1, s_2), d(r_1, r_2)] \quad (3)$$

Now, for a given set of experiments the data consists of a set of stimulus-response pairs: $\{(s_1, r_1), (s_2, r_2), \dots, (s_n, r_n)\}$. As a k th nearest neighbor approach the estimate relies on a choice of a positive integer k . Let $d(i; k)$ be the distance from (r_i, s_i) to the k th nearest data-point, so $d(i; k)$ is the smallest distance such that

$$\begin{aligned} |\{(s_j, r_j) | d[(s_i, r_i), (s_j, r_j)] \leq d(i; k)\}| \\ = k + 1 \end{aligned} \quad (4)$$

where the set has size $k + 1$ rather than k because it includes the point (s_i, r_i) itself. Now let

$$C_S(i) = |\{(s_j | d(s_i, s_j) \leq d(i; k)\}| \quad (5)$$

and

$$C_R(i) = |\{(r_j | d(r_i, r_j) \leq d(i; k)\}| \quad (6)$$

Thus $C_S(i)$ is the number of stimuli with any response within $d(i; k)$ of s_i ; this will, of course, include the k data points counted when defining $d(i; k)$, but it may also include points (s_j, r_j) where $d(s_i, s_j) \leq d(i; k)$ but $d(r_i, r_j) > d(i; k)$. Hence $C_S(i) \geq k$. The same sort of observation applies to $C_R(i)$. Roughly speaking, a separate k -nearest neighbor estimate is calculated for $H(R)$, $H(S)$ and $H(R, S)$ with $C_R(i) - 1$ and $C_S(i) - 1$ playing the role of k for $H(R)$ and $H(S)$. Now, the estimate of the mutual information is

$$\begin{aligned} I(R; S) = & \psi(k) + \psi(n) - \frac{1}{n} \sum \psi[C_S(i)] \\ & - \frac{1}{n} \sum \psi[C_R(i)] \end{aligned} \quad (7)$$

where $\psi(x)$ is the digamma function of x .

If the stimulus space is discrete, the same approach can still give an estimate of the mutual information (Tobin and Houghton 2013). If there are n_s stimuli and each is presented n_t times, the mutual information is

$$I(R; S) = \psi(k) + \psi(n_s n_t) - \psi(n_t) - \frac{1}{n} \times \sum \psi(C_R(i)) \quad (8)$$

In Tobin and Houghton (2013) a similar formula is derived using a kernel-density-estimate based approach. An alternative Kozachenko-Leonenko estimate of the mutual information between a discrete stimulus set and spiking responses is given in Victor (2002).

Definition

Microwires consist of a cylindrical conductor with a diameter on the order of micrometers and, generally, have an insulating sheath. They are commonly used for recording of neural signals or electrical stimulation of nervous tissue.

Detailed Description

Microwires can range anywhere from roughly five to a few hundred microns without insulation. They consist of a conductive material such as pure metals (e.g. gold, Tungsten or stainless steel) or metal alloys (e.g. Pt/Ir or Nichrome). Most pure metals have the advantage of being biologically inert, whereas metal alloys are often favored for their lower cost and better physical properties such as higher flexibility and strength. Typical materials used to electrically insulate the wires from their surroundings are Teflon, Parylene, Formvar, Isonel, polyimide or polyurethane. The insulating layer adds at least 3–7 μm to the wire thickness.

Microwires are available on a spool as single wires or multi-stranded wires where two or more wires are twisted together into a single larger strand. Twisting can be done with either insulated or bare wires depending on the application.

The advantage of microwires for neurophysiological use is that they are relatively inexpensive and can be adapted for use in many different applications. The smaller-diameter, highly flexible microwires also tend to cause less tissue reaction when implanted chronically compared to stiff electrodes and electrode arrays (Bae et al. 2008; Winslow and Tresco 2010; Karumbaiah et al.

2013). This makes them particularly useful in applications like the spinal cord where the tissue not only undergoes micromotion as a result of breathing and heart pulsations but also stretches, contracts and moves significantly within the spinal column when the subject moves.

Stimulation of Neural Tissue

Microwires have been used for intraspinal stimulation for studying spinal networks and the restoration of bladder and movement control (for a review see Bamford and Mushahwar 2011) as well as the stimulation of peripheral nerves (Yoshida and Horch 1993; Lago et al. 2007; Micera and Navarro 2009) and the cortex (Otto et al. 2005; Bretzner and Drew 2005; Nelson et al. 2011).

Recording Use

Single Wires

Depending on their diameter, material and insulation material, single microwires can be stiff enough to be inserted into neural tissue like a needle or they have to be inserted using a guide (Westby and Wang 1997; Tseng et al. 2011). They also have been used in peripheral nerves (Lawrence et al. 2004), spinal cord (Prasad and Sahin 2011) and in cortex (Chang et al. 1988) but the use of arrays of microwires is more common nowadays.

Tetrodes

To improve the isolation of recorded single and multi unit activity, first stereotrodes (McNaughton et al. 1983) with two microwires in close proximity have been developed and then tetrodes (Wilson and McNaughton 1993). For tetrodes, four wires are bundled together in a know pattern and distance from each other. More recently, multiple tetrodes have been mounted in a microdrive assembly where each tetrode can be precisely placed in the neural tissue to further improve recording success (Gray et al. 1995; Nguyen et al. 2009; Santos et al. 2012).

Microwire Arrays

While tetrodes mostly aim to improve recording quality, single wires can also be combined into an electrode array to provide recordings from multiple locations. These arrays are either custom-built or commercially available (Thomas Recording, Tucker-Davis Technologies, Micro-Probes, Alpha-Omega Engineering, Nan Instruments, Neuralynx). One form of multiwire array that allows both tetrode-like and independent single-unit recordings are electrode braids (Kim et al. 2013) in which fine, flexible wires are braided around a stiff, removable core like a sleeve.

There are two types of microwire arrays, one where all wires are spatially arranged and fixed in place before insertion in the tissue (Williams et al. 1999; Rennaker et al. 2005; Zhou et al. 2012) and one where the wires are mounted in an apparatus that allows the movement of individual wires during the experiment (Baker et al. 1999; Kralik et al. 2001; Nicolelis et al. 2003; Jackson and Fetz 2007; Lehew and Nicolelis 2008).

Migraines and Cortical Spreading Depression

Markus A. Dahlem

Department of Physics, Humboldt University of Berlin, Berlin, Germany

Spreading depolarizations

Definition

Migraine is a headache disorder characterized by recurrent episodes of head pain, often throbbing and unilateral, sometimes preceded by neurological symptoms called aura. The known pathophysiologic mechanism suggest that this disorder should be considered as a neurovascular

headache. Migraine is a highly disabling disorder according to the World Health Organization – the seventh most disabling in the world and the fourth most disabling among women.

Spreading depression (SD) is essentially a slow (about 3 mm/min = 50 μ m/s) reaction–diffusion wave in gray matter tissue during which ion concentrations inside and outside the cells change by over one order of magnitude to a nearly complete elimination of transmembrane chemical gradients, i.e., a nearly complete release of Gibbs free energy with depressed neuronal activity. SD is accompanied by a pronounced hemodynamic response of increased regional cerebral blood flow (hyperemia) for about 2 min and a long-lasting, ~2 h, decrease (oligemia).

Detailed Description

Clinical and Pathophysiological Background

In migraine without aura (MO), attacks are usually associated with nausea, vomiting, and sensitivity to light (photophobia) and sound (phonophobia), and attacks are worsened by movement. Migraine with aura (MA) involves in addition nonpainful neurological symptoms (called aura) (Olesen 2013). Migraine aura symptoms are most often visual field disturbances but affect also other sensory modalities or cognitive functions (Vincent and Hadjikhani 2007). Aura symptoms are caused by a wave of cortical spreading depression. Whether this wave also contributes to the headache phase in migraine is currently debated (Karatas et al. 2013, Dalkara and Moskowitz 2017). Epidemiological studies suggest that MA and MO share the same headache phase; however, on average the pain seems to be less severe and shorter lasting in MA than in MO (Rasmussen and Olesen 1992).

The aura phase and pain phase constitute the central part of the attack. Moreover, migraine symptoms can vary across two framing stages, namely, the prodrome and postdrome. Together with the attack-free interval, five phases comprise the migraine cycle with associated severe disabilities and reduced quality of life even between attacks (Brandes 2008). **Aura:** all kinds of fully reversible sensory disturbances, visual is most

frequent. Each individual aura symptom can last 5–60 min. They occur in about 30% of the reported cases. **Headache:** often unilateral and throbbing (though this seems to be not related to blood pulsation). It lasts 4–72 h and occurs in about 95% of the cases. **Prodrome:** feeling tired and weary, difficulty concentrating, yawning, polyuria, sweating, and fatigue are some typical features (Giffin et al. 2003). It lasts up to 1 day and occurs in about 60% of the reported cases. **Post-drome:** tiredness, difficulty concentrating, weakness, dizziness, persistence of sensitivity to light and noise, lethargy, and fatigue together often described as “headache hangover.” It lasts a few days and occurs in about 70% of the reported cases. **Attack-free interval:** In the attack-free migraine, patients exhibit a generalized pressure pain hypersensitivity in the head as compared to healthy controls (Barón et al. 2017).

Before the advent of noninvasive imaging, blood flow changes were thought to be at the origin of the headache phase in migraine. In the 1980s and into the mid-1990s, it became clear by studies of the clinical features of migraine and its physiological mechanisms that there is no clear correlation between blood flow changes and the headache, but instead imaging studies suggested (Weiller et al. 1995) that upstream events in the brainstem named “migraine generator” (MG) (Welch et al. 2001) lead to the cascade activating trigeminal nerve endings leading to migraine pain perception. Furthermore, in migraine with aura, the neural phenomenon of cortical spreading depression was shown by functional imaging to be the neural correlate of migraine aura (Olesen et al. 1981; Hadjikhani et al. 2001).

Migraine Theories

The migraine generator theory states that a dysfunction of the brainstem causes the pain and via further connections (directly and indirectly) the brainstem is also responsible for the neurological changes before the headache phase including symptoms in the prodromal phase and the aura phase, that is, the MG is causing SD via a failure of vasomotor control (Fig. 1a).

The spreading depression theory of migraine assumes that this cortical wave causes the

neurological systems (aura) (Lauritzen 1994) and it can also cause the pain in the headache phase, which usually occurs after the aura phase but cf. Hansen et al. (2012). Two independent pathways are suggested, a peripheral and a central pathway. The headache pain can be triggered by a local release of noxious substances during the hyperemic phase of SD (Karatas et al. 2013). These substances are thought to be transmitted outward in the direction perpendicular to the cortical layers into the pain-sensitive meninges (peripheral pathway, Fig. 1b). This results in an activation of pain receptors (nociceptors) and local inflammation, which triggers the migraine headache. An alternative explanation that could lead to headache induced by SD is a corticothalamic feedback that affects sensory processing by third-order neurons arising within the sensory thalamus. This is supported by the efficacy of calcitonin gene-related peptide receptor antagonists at the level of these neurons in migraine therapy (Summ et al. 2010) (central pathway, Fig. 1c).

The cause of events during migraine cycle are rather complex; in particular, SD drives complex vasomotor effects on cerebral vasculature and may in response be modulated and also initially be caused by cerebral vasculature events (Ayata 2013). Migraine as a chronic disorder with recurrent episodic manifestations should therefore be considered as an inherently dynamical disease to which a simple course of downstream events following on upstream events within a linear arrangement of the involved brain nuclei would not do justice. It rather is a complicated network (see Fig. 1), and sufficient evidence speaks to the fact that both the MG and SD theory of migraine can be validly maintained and that they need to be unified in a network theory.

To this end, a simple dynamically regulated control system was schematically identified and further reduced to a network of the major centers in the brain, including a subnetwork of brainstem nuclei; the trigeminal nerve, which innervates the cranial circulation; parasympathetic vasomotor efferents; and the cortex. This extends the idea of a migraine generator region in the brainstem to a larger network and is still simple

Migraines and Cortical Spreading Depression, Fig. 1 Schematic reduction of the migraine generator network and the effect of cortical spreading depression in migraine. (a) The cranial circulation is connected by first-order perivascular pain-sensitive neurons via the trigeminal ganglion (TG) to the trigeminocervical complex (TCC) and receives also parasympathetic input from vasomotor efferents that may cause SD directly or indirectly via the sphenopalatine ganglion (SPG) and its second-order pre-ganglionic neurons in the superior salivatory nucleus (SSN). (b) Further structures in the brainstem build a

descending modulatory subnetwork that may enhance pain traffic caused by the release of noxious and amatory substances during SD: the rostral ventromedial medulla (RVM), locus coeruleus (LC), periaqueductal gray (PAG). (c) Furthermore, a role of the third-order corticothalamic interactions during SD that might sensitize the central nervous system to react on normal sensory input from cranial circulation with pain (allodynia). This would highlight the role of the thalamus (TH) and also hypothalamus (HY) in migraine

M

and explicit enough to open up possibilities for mathematical modeling, in particular, understanding the complex interactions of cortical SD within other relevant brain structures in migraine (Ayata 2013; Noseda et al. 2010; Akerman et al. 2011; Dahlem 2013). Currently, however, computational models exist only for the cortical event of SD, which are reviewed in the remainder of this entry.

Computational Models of Cortical Spreading Depression

Computational models of spreading depression date back to the mid-1970s. A simple rule-based cellular automata model was used to mimic the two-dimensional spread on the cortical surface, including spiral-shaped SD waves reentering around a functional block (Reshodko and Bures 1975). Partial differential equations were used later to describe the detailed

physiological cellular events (Tuckwell and Miura 1978). There are detailed reviews of computational modeling SD propagation (Miura et al. 2007; Zandt et al. 2015). In this encyclopedia entry, only the very basic approaches that currently are followed can be covered, with a focus on ordinary differential equation for the microscopic local cellular events on a millisecond to second scale and partial differential equations for the macroscopic tissue events that occur on a temporal scale of up to 1 h, that is, the scale of the migraine aura phase.

Cellular Events Caused by SD

The focus in computational models of the cellular mechanisms of SD is on transmembrane events that can be observed, for example, in in vitro experiments without the complex vasomotor feedback involved in SD (Ayata 2013). This in vivo dynamical feedback can be fixed in vitro

by studying, for example, normoxic versus hypoxic spreading depression-like transmembrane cell depolarizations (Somjen 2001). With this focus set, SD is a massive but temporary perturbation of ion homeostasis. The ion concentrations are usually kept within a narrow range of acceptable limits, and their gradient across the cell membrane is treated in traditional computational models of Hodgkin–Huxley (HH) type as a constant battery, the reversal potential or Nernst potential (Hodgkin and Huxley 1952). During SD, however, ion concentrations can change by over one order of magnitude, so that the original HH approach to describe the potential changes across the excitable membrane must be extended. For instance, the extracellular potassium concentration raises from 3 mM within a few seconds to peak values around 55 mM, plateaus at this level for about 30 s, and recovers to the physiological range within 1–2 min (Lauritzen 1994). Furthermore, neuronal activity is depressed due to the nearly complete depletion of the transmembrane ion gradients. This depleted and depressed state can spread through gray matter tissue by electrodiffusion due to newly formed ion gradient along the membranes in the neuronal and glial syncytium and the interstitial volume.

To model local cellular events, we start with Kirchhoff's current law that was introduced as an equivalent membrane circuit by Hodgkin and Huxley (1952):

$$\frac{dV}{dt} = -\frac{1}{C_m} (I_{Na^+} + I_{K^+} + I_{Cl^-} + I_{pump} - I_{app}). \quad (1)$$

The variable V is the potential difference or voltage across the membrane relative to the grounded extracellular side. The cell membrane has a capacitance C_m . The currents I_{ion} are the transmembrane currents with the index $ion \in \{Na^+, K^+, Cl^-\}$. I_{app} is an externally applied current.

In the original HH framework, an unspecified leak current was modeled but not a chloride current. The major extension, however, is the pump current I_{pump} , which can be modeled, for example, as (Cressman et al. 2009):

$$I_{pump}(Na_i, K_e) = \rho \left(1 + \exp \left(\frac{25 - Na_i}{3} \right) \right)^{-1} (1 + \exp(5.5 - K_e))^{-1}. \quad (2)$$

The pump current I_{pump} describes the ATP-driven exchange of intracellular sodium ions with extracellular potassium at a 3:2 ratio.

The ion concentrations ($[ion]$) change due to fluxes proportional to the ion currents. The additional rate equations for intracellular ion concentrations are:

$$\frac{d[ion]}{dt} = -\frac{\gamma}{\omega} (I_{ion} + \alpha I_p), \quad (3)$$

with α being 3, 2, and 0 for Na^+ , K^+ , and Cl^- , respectively. The parameter γ converts currents to ion fluxes and depends on the membrane surface area A_m and Faraday's constant F , $\gamma = A_m/F$. The parameter ω is the volume of the intracellular space (ICS).

In addition, also dynamical gating variables n , h , and m have to be introduced, as in the original HH model. The potassium activator, sodium activator, and sodium inactivator are defined by the voltage-dependent gating dynamical variables n , m , and h , respectively. These are given by $p \in \{n, m, h\}$:

$$\frac{dp}{dt} = \frac{1}{\tau_p} (p_\infty - p) \quad (4)$$

For the detail of the voltage-gating mechanism, see the article of the HH model. The HH model is sometimes also called a conductance-based model, while, in contrast, neural mass models are called rate based or activity based. In each case, the model is named after the respective dependent dynamical variables other than the transmembrane potential V . In this terminology, the second-generation HH models described by Eqs. 1, 2, 3, and 4 are ion-conductance-based models.

With a minimal ion-conductance-based model of a total of only four dynamical variables, the main features of SD across the cell membrane can

be modeled. Using electroneutrality and further symmetry constraints, ion-conductance-based models can be reduced. However, more physiological detailed models of SD are given by ion-conductance-based models with 9–29 dynamical variables in various (~ 200 , which effectively multiplies the number of dependent dynamical variables) electrically coupled neural compartments (Miura et al. 2007; Kager et al. 2000; Shapiro 2001).

Although in the minimal ion-conductance-based model, the time course of the dynamical variables can be lightly distorted as compared to more realistic models (Miura et al. 2007; Kager et al. 2000; Shapiro 2001; Somjen et al. 2008); the main features of SD are revealed. In Fig. 2, the nine dynamical variables are the membrane potential, two gating variables, and six ion concentrations. During the course of SD (Fig. 2), two phases and three points stand out because of their significant mechanistic meaning in SD as an excitation phenomenon: the seizure-like afterdischarges, the subsequent excitation block, the beginning of an I_{Na} -driven transient repolarization, and the m-gate deactivation that finally initiates a phase where the pump current I_{pump} can become dominant.

Migraines and Cortical Spreading Depression, Fig. 2 Time course of transmembrane potential (black) and Nernst reversal potential for Na^+ (red) and K^+ (blue) in a minimal ion-conductance-based second-generation Hodgkin-Huxley model following a brief (0.5 s) stimulation (gray). For further details, see text

In hypoxic conditions, these phases can be quite different; in particular the point of the m-gate deactivation can be missed resulting in tissue infarct. However, only the normoxic migraine condition and their corresponding electrophysiological mechanism of ignition and recovery in SD can be described here. For more details, the reader is referred to the review by Miura et al. (2007).

Of all these events highlighted in Fig. 2, maybe the most notably is the recovery phase of SD at around ~ 24.5 min. According to the computational models, recovery is due to a deactivation of the sodium activator m driven by a dominate sodium current I_{Na} that actually repolarizes V a few seconds after the seizure-like firing stops due to a depolarization block. After the deactivation of sodium activator m, the pump current I_{pump} drives the membrane potential for several seconds outside the window of the two reversal potentials of Na^+ and K^+ , red and blue curves, respectively. The ignition of SD is due to a torus bifurcation (not shown) of the tonic seizure-like firing. The seizure-like firing is caused by the initial stimulation phase. However, after the offset of the stimulation at 0.5 s, the state of the dynamical system is already behind a canard-like sharp threshold trajectory causing firstly a brief phase of sustained (2–3 s) afterdischarges. Only then a long-lasting (~ 0.5 h) recovery phase begins during which the system is refractory.

Before we consider large-scale tissue events caused by SD, it is worth noting that cellular models often do not include lateral space, except for the original work by Tuckwell and Miura (1978) and some modern approaches from the group of Miura (Yao et al. 2011) and an isolated work by Shapiro (2001) considering osmotic forces and gap junctions. The compartments mentioned before extend in the vertical direction to model the apical dendritic tree of pyramidal cells in the cortex (Kager et al. 2000; Somjen et al. 2008). But the very detailed models by Kager, Wadman, and Somjen are not spatially extended to describe the lateral extension, that is, they describe SD not as an excitable phenomenon in a spatially extended system, called excitable media.

The lateral extension of cellular SD models is far from straightforward. Naively adding diffusion to the extracellular dynamical ion concentrations yields some insights, but it does not reflect the necessary detail that needs to be considered to take the spatial continuum limit. Neural field models, for example, describe this limit for rate- or activity-based neural models (Bressloff 2012). The problem is that the neural tissue is heterogeneous. A bottom-up approach toward an ion-conductance-based medium model that lacks the support of an effective medium theory cannot expand from membrane to tissue level in a canonical way and therefore loses its advantage over the simpler top-down approaches. Likewise, a coarse graining in time from individual spiking to rate- or activity-based dynamics in simulated cell populations is needed for the relevant time scales in migraine.

Tissue Events Caused by SD

In accordance with noninvasively imaged SD progression using high-field functional magnetic resonance imaging (Hadjikhani et al. 2001) and reported visual field defects (Dahlem and Hadjikhani 2009), a macroscopic computational model of SD was proposed in which in each episodic migraine attack with aura, a particular spatiotemporal SD pattern is formed (Dahlem and Isele 2013). Such heterogeneous propagation

of SD has later been also discovered in the lissencephalic and gyrencephalic brain (Santos et al. 2017).

In the proposed macroscopic computational model of SD, the wave front takes the shape of a discontinuous wave segment that spreads out only in one direction. These heterogeneous propagation patterns are the tissue events that are of clinical importance for migraine. Note that reentrant SD waves are of clinical relevance under conditions of stroke, where repeated SD waves are believed to have the potential to worsen outcome in incremental steps with each wave circling near the infarct core (anatomical block) but could also have some beneficial component by stimulating blood flow in the penumbra zone far from the infarct tissue (Dahlem et al. 2010). A major advantage of generic, i.e., low-dimensional, reaction–diffusion models lies in the fact that they provide insight in the phase-space structure of the whole class of models they represent. Various pattern-forming mechanisms can be understood in terms of phase-space structures that describe the migraine aura-ischemic stroke continuum as transitions from two-dimensional wave pattern in SD, from retracting (migraine) via reentrant (stroke) to stationary waves (persistent migraine aura without infarct); see for retracting SD waves Fig. 3.

To simulate the clinically observed patterns in migraine (Hadjikhani et al. 2001; Dahlem and

Migraines and Cortical Spreading Depression, Fig. 3 Schematic sketch of phase spaces: (a) excitable media support traveling wave solutions (red point) that are separated from the stable homogeneous steady state (green point) by the stable manifold (blue surface) of critical nucleation solutions (white point, saddle); (b) in excitable media with mean field control of a threshold

parameter (cf. β in Eq. 6), the control can be adjusted such that the branch (using β as a bifurcation parameter) of the nucleation solution folds and is partly stabilized; and (c) the medium with mean field control and control parameters such that the system is beyond the fold point, that is, there exists a ghost of the saddle-node bifurcation still influencing the dynamics by a critical slowing down

Hadjikhani 2009), a generic reaction–diffusion mechanism can be described in abstract terms of activator–inhibitor kinetics of just two variables u and v , respectively. In fact, simple activator kinetics of u date back to a mechanism of SD described in 1963 by Grafstein, Hodgkin, and Huxley GHH (Grafstein 1963). The GHH model assumed that $u = [K^+]_e$, i.e., the extracellular potassium ion concentration, is the activator u in SD. We extended this scheme in the following way (for details of the full model, see Dahlem and Isele (2013)):

$$\varepsilon \frac{\partial u}{\partial t} = u - \frac{1}{3}u^3 - v + \nabla^2 u, \quad (5)$$

$$\frac{\partial v}{\partial t} = u + \beta + K \int H(u) dx dy, \quad (6)$$

with H being the Heaviside step function. Both activator u and inhibitor v are lump variables. Unlike in the original GHH model, it is not necessary or even possible to identify particular physiological quantities, like $[K^+]_e$, with them. Instead, the activator u should be viewed as the bistable energy state. One stable fixed point corresponds to the maintenance of homeostasis far from thermodynamic equilibrium and the other stable fixed point to the state where the cellular Nernst reversal potentials are depleted (thermodynamic equilibrium). In the presence of an inhibitor v , which was not included in the GHH model, the second stable fixed point becomes a transient state. In other words, the inhibitor v is a recovery variable. It is related to ion buffering and ion pumps (Hübel et al. 2014, Hübel and Dahlem 2014) that drive the tissue far from thermodynamic equilibrium and (re)charge Nernst reversal potentials. We set the parameter as follows: the time scale separation, $\varepsilon = 0.04$; the threshold, $\beta = 1.32$; and the mean field coupling, $K = 0.003$, to obtain the patterns shown in Fig. 4.

To summarize, the reaction–diffusion patterns simulated by Eqs. 5 and 6 (Fig. 4) are macroscopic manifestations of SD, which is on a microscopic cellular level described by electrophysiological ionic events simulated by Eqs. 1–5. The pathological state in migraine arises from complex

Migraines and Cortical Spreading Depression, Fig. 4 Spatiotemporal signatures of SD as obtained from a generic reaction–diffusion model with mean field coupling, Eqs. 5 and 6. There are two cases where the SD front does not break open: (1) subthreshold, SD dies out quickly without initial spread; (2) superthreshold perturbation, SD dies out after less than 5 min at the propagation boundary δP (see text), corresponding according to the diagnostic criteria of headache to migraine without aura (MO). Two examples where SD front does break open, corresponding to migraine without aura (MA): (3)–(4) suprathreshold perturbation, SD propagates for up to 25 min in (3) and ~15 min in (4) possibly with less or no severe pain experience (migraine with typical aura without headache)

processes that interact over these large-range spatial and temporal scales and from interaction with subcortical central brain structures and peripheral innervation of the cranial circulation. We still lack a thorough theoretical framework to interpret these events to fully realize the potential of computational models in migraine. The challenge in the future will be to integrate these into a tractable migraine model.

Definition

MIIND (Multiple Interacting Instantiations of Neural Dynamics) is a neural simulator that allows the creation of large-scale neuronal networks at the population level. Populations of neurons are considered to be homogeneous and comprised of point model neurons. MIIND does not simulate individual neurons but considers their distribution over the model neuron's state space in terms of a density function and models the evolution of this density function in response to input from other neural populations or external input. From the density function, other quantities can be calculated, such as the population's firing rate. This rate, in turn, can influence other

populations. Because populations interact through firing rates rather than individual spikes, the simulation of networks of spiking neurons becomes easier as no events need to be buffered. Using an XML format, it is easy to configure large-scale network simulations. MIIND is implemented as a C++ package but has a Python interface so that simulations can be driven and results can be analyzed in Python. It has been used in the simulation of networks of language representation and spinal cord circuits.

Detailed Description

MIIND (de Kamps et al. 2008) is a simulation package that can be driven from Python through an XML file. It can simulate complex circuits of neural populations. It stands out from other simulation packages in that it (i) models directly at the population level; (ii) uses population density techniques (PDTs) to model the state and firing rate response of the population; and (iii) offers the capability to incorporate existing and novel two-dimensional (2D) point model neurons into its framework.

Most population-level simulations described in the literature use rate-based modeling: a population is characterized by a single variable, such as firing rate or average membrane potential. A network simulation based on these methods usually results from the solution of a coupled set of first-order ordinary differential equations. A prominent example of such a system are the Wilson-Cowan equations (Wilson and Cowan 1972). There are efficient solution methods for large coupled networks, and their use is appropriate when considering quantities that are only indirectly related to the neural substrate, for example, in modeling imaging techniques where they have found widespread application.

Sometimes reducing the state of a population to a single variable is too restrictive and leads to the wrong simulation results (Montbrió et al. 2015). One option is to perform spike-based simulations, using neural simulators such as NEST or BRIAN (we will not discuss compartmental modeling here).

When applied to large-scale networks, these simulations can become unwieldy, in terms of the number of parameters required or resources (CPU, memory) consumed. A good compromise is to use *population density techniques* (PDTs). PDTs are based on point model neurons, such as leaky integrate-and-fire (LIF), which are one dimensional as the only variable characterizing their state is the membrane potential. Richer models usually have more variables defining the neuronal state, e.g., the FitzHugh-Nagumo model has two and is therefore referred to as 2D, and so does the adaptive-exponential-integrate-and fire (AdExp), while the Hodgkin-Huxley model has 4. In a detailed NEST simulation, it would be possible to follow individual neurons as they move through state space, driven by their own dynamics, as well as by the effects of incoming spikes from other neurons. A large population can then be imagined as a cloud of points in the state space of the model neuron if this population is assumed to be homogeneous – and the neurons have the same state space. An example is given in Fig. 1, which tracks the state of individual AdExp neurons over time. Although the individual neurons, represented by green points, are kicked around state space by incoming spikes and their state is unpredictable as these incoming spikes are modeled as random events, the behavior of the entire cloud of neurons is far more predictable, so much so that one can define a density function that represents the probability of finding a given neuron in state space. Using statistical techniques, one can model the evolution of this density function directly, without the need for keeping track of individual neurons, purely based on the dynamics of the point model neuron and the characteristics of the statistics governing spike trains that arrive at the neuron. A good introduction to PDTs can be found in Omurtag et al. (2000).

A major advantage of PDTs is that they represent the neuronal state of the population faithfully, something that cannot be said of rate-based models. In some cases, this leads to radically different predictions for the same network connectivity. A disadvantage of PDTs is that they are computationally more expensive than rate-based

models. They tend to be more efficient than direct simulations however, both for one- and two-dimensional models. For higher dimensional models, like Hodgkin-Huxley, PDTs are still computationally inefficient, as they suffer from the curse of dimensionality, although a more intelligent representation of state space may make them viable in the future. At the moment, there is a trend in computational neuroscience to reduce complex neuronal dynamics, described by high-dimensional systems to two-dimensional ones, as these retain the essence of the higher dimensional ones but are easier to visualize and analyze. 2D PDTs appear a good compromise between computational efficiency and expressivity of the neural model. Recently, we have made considerable progress in the solution of network equations for 2D PDTs (de Kamps et al. 2019).

MIIND and DIPDE (Allen Institute for Brain Science n.d.) are the only simulators, to our knowledge, that are based on PDTs. Where DIPDE is restricted to one-dimensional model (LIF), MIIND can use 2D point model neurons, as well as 1D models, such as leaky integrate-and-fire, quadratic integrate-and-fire, and others, which in the MIIND framework emerge as specializations of 2D models. The introduction of a new model MIIND is very easy: it requires a representation of the flow field of the model in terms of an ASCII file in a predefined model but does not require programming. As such it is a great tool for studying noise in 2D dynamical systems, not just neurons.

We have performed comparison studies and found that large networks of 1D neurons, such as LIF and QIF, can be simulated much faster than by simulating spikes individually. For 2D models, the run times are similar to NEST, but memory use is at least an order of magnitude lower than when simulating individual neurons. We have provided a CUDA implementation, which means that a network comprised over thousands of populations can be run on a single PC, equipped with GPU, rather than on an HPC cluster. MIIND is available at: miind.sf.net, where the code and training materials can be found.

Definition

Mixed-mode oscillations (MMOs) in neuronal systems are oscillatory patterns of activity

consisting of subthreshold (or membrane potential) oscillations interspersed with action potentials (or spikes).

Detailed Description

Introduction

Rhythmic oscillations in the theta (4–12 Hz) and gamma (30–100 Hz) frequency bands have been recorded in the hippocampus and the entorhinal cortex and have been implicated in cognitive processes including memory, spatial navigation, and sleep (Buzsáki 2002, 2006; Kahana et al. 1999; O’Keefe and Recce 1993; Traub and Whittington 2010; Buzsáki and Wang 2010; Engel et al. 2003; Fries 2009; Singer and Gray 1995; Bragin et al. 1995; Montgomery and Buzsáki 2007). These network oscillations emerge from the cooperative activity of the participating neurons and network connectivity.

Intrinsic subthreshold (membrane potential) oscillations (STOs) and MMOs at theta and gamma frequencies have been observed in various neuron types (Alonso and Llinás 1989; Chapman and Lacaille 1999; Dickson et al. 2000a, b; Leung and Yim 1991; Fransén et al. 2004; Schmitz et al. 1998; Yoshida and Alonso 2007; Bourdeau et al. 2007; García Muñoz et al. 1993; Llinás et al. 1991). MMOs have been most notably investigated in stellate cells in layer II of the medial entorhinal cortex (Fransén et al. 1998; Fernandez and White 2008; Giocomo et al. 2007; Yoshida and Alonso 2007).

Several models have been used to investigate MMOs (Wang 2002; White et al. 1998; Fransén et al. 2004; Acker et al. 2003; Rotstein et al. 2006, 2008; Jalics et al. 2010; Medvedev and Cisternas 2004; Dorval and White 2005; Brøns et al. 2008; Desroches et al. 2012; Morin et al. 2010). These models focus on the role of the ionic currents in shaping the MMO patterns (generation of STOs and the onset of spikes) or the dynamic mechanisms that give rise to MMOs.

The functionality of MMOs is still a matter of discussion. STOs have been argued to function as a timing device (Lampl and Yarom 1993) and to play a role in spatial navigation (Giocomo et al.

2007). While action potentials (or spikes) are the basic neuronal signaling mechanism (Johnston and Wu 1995; Koch 1999; Dayan and Abbott 2001; Ermentrout and Terman 2010), the interspersed STOs in the MMO patterns (Figs. 1 and 2) may help create a time scale at which information is effectively communicated among neurons.

The Structure of MMO Patterns

Typically, a basic MMO cycle consists of s small amplitude oscillations followed by L spikes (or vice versa). The notation L^s is customarily used to describe these patterns (Desroches et al. 2012; Bröns et al. 2008) (and papers therein).

Mixed-Mode Oscillations in Single Neurons,

Fig. 1 MMO patterns in a 2D STO-F model with linear subthreshold dynamics (see also resonate-and-fire models (Izhikevich 2001)). The subthreshold dynamics are governed by the following two equations describing the dynamics of the rescaled voltage V (mV) and gating variable w (mV) (see (Richardson et al. 2003)): (i) $CdV/dt = -g_L V - gw + I_{app}$ and (ii) $\tau dw/dt = v - w$. Spikes are added manually when V reaches V_{th} , and V and w are reset to V_{rst} and w_{rst} respectively. (a) The reset values V_{rst} and w_{rst} are constant and independent of the number of spikes. (A1) $I_{app} = -0.2$. (A2) $I_{app} = 0$. (A3) $I_{app} = 0.2$. We used the following parameter values: $C = 1$, $g_L = -0.03$, $g = 0.3$, $\tau = 40$, $V_{th} = 10$, $V_{rst} = -5$, $w_{rst} = -1$. Units are as in

(Richardson et al. 2003; Rotstein 2013). (b) The reset value w_{rst} changes as a function of the number of consecutive spikes (N) according to the following rule: when $N = N_{max}$, w_{rst} is decreased by an amount Δw_{rst} . (The reset value V_{rst} is constant and independent of the number of spikes). (B1) $N_{max} = 2$ and $\Delta w_{rst} = 1.5$. (B2) $N_{max} = 2$ and $\Delta w_{rst} = 2.5$. (B3) $N_{max} = 2$ and $\Delta w_{rst} = 3$. (B4) $N_{max} = 3$ and $\Delta w_{rst} = 2.1$. (B5) $N_{max} = 3$ and $\Delta w_{rst} = 2.7$. (c) The reset values V_{rst} and w_{rst} are constant and independent of the number of spikes (as in A). $I_{app} = -0.2 + \sqrt{2D} \eta(t)$ where the last term is white noise (delta correlated) with zero mean and standard deviation D . We used $D = 0.2$. Other parameter values are as in A

MMO patterns can be regular (Figs. 1a, b) or irregular (Fig. 1c). In turn, regular MMO patterns can be uniform, where the sequence L^s describes the MMO patterns in their entirety (Fig. 1a), or nonuniform, where MMO cycles consist of sub-cycles described by sequences of the form $L_1^{s_1} - L_2^{s_2} - \dots - L_N^{s_N}$ (for some integer N) (Fig. 1b). Irregular MMO patterns can be either stochastic (Fig. 1c) or chaotic (not shown).

The occurrence of L^0 cycles (for $L > 1$) embedded in MMO patterns, with two or more consecutive spikes with no interspersed STOs (Figs. 1B2, B5, C), is customarily referred to as spike clustering (Fransén et al. 2004; Alonso and Klink 1993; White et al. 1998; Serafin et al. 1996; Desmaisons et al. 1999; Wang 2002; Muratov and Vanden-Eijnden 2008; Kuske and Borowski 2009). The inter- and intra-spike frequency may belong in the same frequency range or not depending on the neuronal type and other parameter values.

Dynamic Mechanisms of Generation of MMOs

The generation of MMO patterns requires the coordinated action of various mechanisms: (i) a mechanism for the generation of STOs; (ii) a spiking mechanism, including the onset of spikes and the description of the spiking dynamics; and (iii) a return mechanism from the spiking regime back to the subthreshold regime.

The minimal models able to generate intrinsic oscillatory behavior are 2D and involve the dynamics of the voltage v and a recovery variable (w) (Rinzel and Ermentrout 1998; Rinzel 1985; Ermentrout and Terman 2010; Ermentrout and Kopell 1998; FitzHugh 1961; Nagumo et al. 1962). These models may generate either STOs (Fig. 3a) or spikes (Fig. 3b) but not MMOs. MMO patterns require an additional mechanism that describes the dynamic transition between these two regimes. This mechanism may be provided by an external input (non-autonomous system), such as in certain cases of the slow passage through a Hopf bifurcation (Holden and Erneux 1993; Baer et al. 1989) and the patterns resulting

from oscillatory forcing (Barnes and Grimshaw 1997; Shimizu et al. 2012), or by an additional dependent variable (autonomous system) (Fig. 3c) as in the 3D canard phenomenon (Wechselberger 2005; Brøns et al. 2006).

The minimal models that are able to generate intrinsic MMOs are nonlinear, 3D, and involve multiple time scales. The prototypical example is the 3D extended version of the FitzHugh-Nagumo (FHN) model (FitzHugh 1961; Nagumo et al. 1962) (Fig. 3) describing the dynamics of the voltage v and two gating variables (w and z) with linear dynamics. Models of FHN type are caricature models, but they capture the basic dynamic properties observed in detailed biophysical (conductance-based) models.

In the example presented in Fig. 3, all the MMO mechanisms are described by the same model. The generation of STOs (Fig. 3A3) and the onset of spikes (Fig. 3B3) are governed by the locally parabolic portion of the v -nullcline, near its minimum. The spiking dynamics and the return mechanisms are primarily governed by the right and left branches of the v -nullcline respectively (Fig. 3A2). The abrupt transition from STOs to spikes is due to the 2D (Figs. 3a, b) and 3D canard phenomena (Figs. 3c) (Krupa and Szmolyan 2001; Wechselberger 2005; Brøns et al. 2006). The locally parabolic nonlinearity at the minimum of the v -nullcline and the time scale separation between v and the remaining dependent variables are key for these mechanisms.

Higher-dimensional models provide the necessary flexibility for the generation of more complex MMO patterns. Typically, in these models each mechanism (e.g., STOs, spikes) is described by a different, lower-dimensional regime (Rotstein et al. 2006).

Generalizations of the integrate-and-fire model to include 2D linear subthreshold dynamics (Izhikevich 2001; Richardson et al. 2003; Rotstein 2013) are able to produce MMOs provided that the fixed-point of the underlying (subthreshold) 2D linear system is an unstable focus (Rotstein 2013). (Stable foci are possible in the stochastic case). These models are referred to as STO-F models (STO-and-fire models)

(Rotstein 2013). The mechanism of spike generation consists of a voltage threshold (V_{th}) and “artificial spikes”: spikes are added manually when the voltage V crosses V_{th} . The return mechanism consists on the manual reset of V and w to predetermined values V_{rst} and w_{rst} after a spike has occurred. STO-F models with constant values of w_{rst} generate regular uniform 1st MMO patterns (Fig. 1a) where the number of STOs per cycle depends on the model parameters. The generation of regular nonuniform MMO patterns requires a return mechanism where at least one reset value (either V_{rst} or w_{rst}) is not constant and depends, for instance, on the number of consecutive spikes within some range (Fig. 1b).

Generalizations of the integrate-and-fire model to include 2D or 3D nonlinear subthreshold dynamics, such as the reduced medial entorhinal cortex layer II stellate cell model (Rotstein et al. 2006) and extensions of the quadratic-integrate-

and-fire models (Izhikevich 2001, 2006; Rotstein et al. 2006, 2008; Jalics et al. 2010), typically have a parabolic-like voltage nullcline in the subthreshold regime, and the gating variables have either linear or sigmoidal nullclines (Izhikevich 2001, 2010; Rotstein et al. 2006). These models are able to generate STOs provided the fixed-point in the subthreshold regime is a focus. In addition, these models describe the onset of spikes, but not the spiking dynamics. The voltage threshold V_{th} indicates the occurrence of spikes, which are added manually. (Note that V_{th} is not a part of the spiking generation mechanism). The voltage and possibly the gating variables are reset after a spike has occurred (return mechanism). In principle, MMOs are possible when the subthreshold dynamics are 2D provided the reset point (V_{rst} , w_{rst}) is close enough to the fixed-point and the latter is unstable, thus generating a spiraling out solution. However, for biophysically plausible

Mixed-Mode Oscillations in Single Neurons, Fig. 2 MMO patterns in 3D parabolic STO-F models with a parabolic nonlinearity in the voltage equation. The subthreshold dynamics is governed by the following three equations describing the dynamics of the rescaled voltage V and gating variables w and z : (i) $dV/dt = V^2 - w + I_{app}$, (ii) $\tau dw/dt = 0.5 * V - w$, and (iii) $\tau dz/dt = \eta$ (panels A) and $\tau dz/dt = \eta (0.5 V + 0.02 - z)$ (panels B). The onset of spikes is described by the equations describing the

subthreshold dynamics. The occurrence of spikes is indicated when V reaches V_{th} , and V , w , and z are reset to V_{rst} , w_{rst} , and z_{rst} respectively. For $\eta = 0$, the corresponding 2D systems display damped STOs. (A1) $I_{app} = -0.008$. (A2) $I_{app} = -0.006$. (A3) $I_{app} = -0.004$. (B1) $I_{app} = -0.004$. (B2) $I_{app} = -0.003$. (B3) $I_{app} = -0.0027$. We used the following parameter values: $\tau = 100$, $V_{th} = 1$, $V_{rst} = -0.1$, $w_{rst} = V_{rst}^2 + I_{app} - 0.001$, $z_{rst} = 0$, $\eta = 0.0003$ (A), and $\eta = 0.1$ (B).

situations, this condition is not satisfied, and an additional subthreshold variable (z) is required to govern the dynamic transition from STOs to spikes (Fig. 2). The slow component of the h-current plays this role in the stellate cell model mentioned above (Rotstein et al. 2006, 2008), while a persistent sodium and the fast component of the h-current are enough to generate STOs.

The mechanisms of generation of MMOs in conductance-based models when different sets of ionic currents govern the dynamics of the subthreshold and spiking regimes are more difficult to analyze due to their high dimensionality. There

are circumstances where the dynamics for different regimes can be treated separately by using reduction of dimensions methods (Rotstein et al. 2006).

The mechanism of generation of MMOs crucially depends on the mechanism of transition from STOs to spikes. Several mechanisms have been described in the literature (Guckenheimer et al. 1997; Wechselberger 2005; Guckenheimer 2008a, b; Krupa and Wechselberger 2010; Koper 1995; Larter and Steinmetz 1991) in addition to the canard phenomenon (Szmolyan and Wechselberger 2001; Wechselberger 2005;

Mixed-Mode Oscillations in Single Neurons, Fig. 3 STOs, spiking, and MMOs in models of FitzHugh-Nagumo type. (a) STOs ($\lambda = 0.0075$) and (b) spiking ($\lambda = 0.008$) for the 2D FHN model described by the following equations: (i) $dv/dt = -2v^3 + 3v^2 - w$, (ii) $dw/dt = 0.01(4v - \lambda - w)$. (c) MMOs for the extended, 3D FHN model described by the following equations:

(i) $dv/dt = -2v^3 + 3v^2 - w$, (ii) $dw/dt = 0.01(4v + 0.02 - z - w)$, (iii) $dz/dt = 0.0005(4v + 0.9 - z)$. *Left panels:* voltage time courses. *Middle and right panels:* phase planes. The *right panels* are magnifications of the *middle ones*. Panel C3 corresponds to the projection of the phase-space (for the variables v , w , and z) onto the v - w plane

Brøns et al. 2006; Rotstein et al. 2006) and the slow passage through a Hopf bifurcation (Larter et al. 1988; Holden and Erneux 1993; Baer et al. 1989). These mechanisms are reviewed in (Desroches et al. 2012).

We note that MMOs have also been observed in other fields of science including chemistry and biology (Petrov et al. 1992; Aguda et al. 1989; Hauser and Olsen 1996; Strizhak et al. 2002; Baba and Krischer 2008). In these cases MMOs consist of an alternation of small amplitude oscillations (SAOs) and large amplitude oscillations (LAOs) where the amplitude between SAOs and LAOs differs roughly by an order of magnitude.

Definition

ModelDB is a database that supports the development of the field of computational neuroscience by storing and making available the computer code for publications that contain biophysical models of neurons and microcircuits. The focus is on models of biologically realistic neurons and circuits, but the spatial scales also range from molecules (ion channels and receptors) through behavior (dynamical systems, including an organism and its environment). The complexity of these mathematical models makes it challenging to recreate the simulations described in the papers from scratch, due to incomplete or ambiguous information in the paper or to errors introduced in attempting to recreate the model. Having the author's original code or a third-party contribution available for download is invaluable for recreating a model for verification, extending the model, and reusing the model as a template or building block for new research projects.

Detailed Description

ModelDB began in the Shepherd lab at Yale University in 1995 (Peterson et al. 1996) with the goal of supporting the development of computational neuroscience by sharing simulation computer code. The importance of computational models for integrating neuroscience data was envisaged in the original Human Brain Project (see Pechura and Martin 1991). ModelDB has been supported under the original Human Brain Project, which provided crucial early support for the development of neuroinformatics tools in support of neuroscience research, including the integration of neuroscience data into computational models.

Many of the model entries of channels and receptors are descendants of the original Hodgkin–Huxley model (Hodgkin and Huxley 1952) of the sodium, potassium, and leak currents which generate the squid axon action potential. The modeling methods that extended studies of neuronal electrical activity from “point” neurons to passive and active dendrites and axons (represented as tapering cylindrical cables) were introduced in neuroscience by Wilfrid Rall, with the first applications to brain neurons in the olfactory bulb (Rall and Shepherd 1968). Initially built to store and share models of neurons in the olfactory system, the main topic of research in the Shepherd lab, ModelDB was quickly broadened to include investigators who contributed their published model computer code of neurons in many other regions of the nervous system.

These broadened contributions have rapidly expanded the database as can be seen in Fig. 1; from a modest number in 2001, the inventory of models has risen steadily over 12 years at an annual rate of about 70. The first method was for the curator to solicit authors of articles containing the models, and this method continues. However, in recent years there has been a steady increase in unsolicited submission of models by the authors themselves, who then work with the curator to insure accurate incorporation into the database. In parallel with this rise has been a rise in the citations of ModelDB in the literature (currently over 360, see Fig. 2) as a place where code was obtained, or deposited, or is mentioned in a

ModelDB, Fig. 1 Total number of models in ModelDB

ModelDB, Fig. 2 Total number of papers that cite ModelDB. In red are the portion of papers published by the ModelDB group

neuroinformatics context. These two trends indicate the growing recognition of the critical role that models are playing in modern neuroscience.

ModelDB contains functionality that enhances the value of the database by providing search tools for different purposes. As can be seen on the home page (Fig. 3), the user can search on, for example, neuronal type, brain regions, receptors and channels, and a wide variety of topics, which include plasticity, depolarization block, synchronization, and magnetoencephalography among many. These tools are under continual development to assist users in finding models of interest. Within the topics, “microcircuits” has undergone a particularly robust development in recent years (see Handbook of Brain Microcircuits, Shepherd and Grillner 2010), so that a new database

ModelDB provides an accessible location for storing and efficiently retrieving computational neuroscience models. ModelDB is tightly coupled with [NeuronDB](#). Models can be coded in any language for any environment. Model code can be viewed before downloading and browsers can be set to auto-launch the models. For further information, see [model sharing in general](#) and [ModelDB in particular](#).

ModelDB, Fig. 3 ModelDB home page

(MicrocircuitDB) on this topic alone has been created and now contains over 180 models.

Another type of search tool enables the user to find models by different model environments, which currently total over 70 different applications. The most numerous is NEURON (398) (Hines and Carnevale 2013) whose authors are key members of the SenseLab group. Also numerous are MATLAB (185), C or C++ (88), XPP (73), GENESIS (31), and Python (23). The extraordinary variety of modeling environments is evidenced by the fact that there are a large number of model entries created by only one or two applications (46).

A significant barrier to effective model sharing is the effort that a user must invest to decide whether a particular model is applicable. It is one thing for a model author to say “this program creates a model of a pyramidal cell” and quite another to know exactly what anatomical and biophysical properties are represented in that model. Source code is essential but can be difficult to analyze, and variables may have values at run

time different from the first values indicated in the top of the code. A new web-based “ModelView” tool that provides ModelDB users with a browsable graphical and textual summary of the anatomical and biophysical attributes of a model is being developed. ModelDB’s ModelView does this without requiring the user to install a simulator or other specialized software and even without having to download model source code from ModelDB; the only prerequisite is a web browser and Internet access. This helps modelers develop a conceptual understanding of a model much faster and with far less effort than required to understand code.

This tool was inspired by, and makes use of, the NEURON simulation environment’s own ModelView tool. The prototype implementation was used to generate pilot data from three models in ModelDB, available through a “Model View” link for these models (McDougal et al. 2013); for example, click on Model View in <http://senselab.med.yale.edu/ModelDB/ShowModel.asp?model=87284>.

Another problem commonly faced by modelers is how to identify ion channels that are appropriate for their own modeling projects. The proliferation of data on membrane ion channels enables models of channels and their contributions to neural function to be increasingly accurate. By the same token, it presents serious challenges in the form of multiplicity of channel subtypes, duplication of subtypes in different models, and searchability for specific model subtypes for a given type of neuron model of interest. To solve this problem, ModelDB has begun using a direct comparison of file contents to identify duplicate files. This method allows tagging filenames with an asterisk suffix in the model-viewing page, ShowModel.asp, which have been found to be duplicated (present in other entries in ModelDB). Identification of reused ion channels and receptors in different models in ModelDB will help investigators assess channel mechanisms in their larger context of (sometimes widespread) use in different types of cells.

Modeling Cerebellar Learning: Input Minimization

Thomas J. Anastasio

Department of Molecular and Integrative Physiology, and Beckman Institute, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Input minimization (InMin) is a learning algorithm that can be used to train neural networks to accomplish time-varying input–output transformations. InMin is also a plausible model of cerebellar learning. The model represents the major cerebellar cell types and connections: Purkinje cells, stellate cells, granule cells, mossy fibers, parallel fibers, climbing fibers, and deep cerebellar or vestibular nuclei neurons. InMin uses a combination of two learning mechanisms to train connection weights in the cerebellar network: the parallel-Purkinje weights are trained using the self-organizing map algorithm, while the stellate-Purkinje or Purkinje-nuclear weights are trained using a form of reinforcement learning. Through these mechanisms the Purkinje cells each learn to specialize for their own segment of the time-varying input and to adjust the strength of their contribution in order to reduce both error and effort in accomplishing the input–output transformation. Unlike almost all other models of cerebellar learning, climbing fibers in InMin do *not* carry error signals. Instead, error signals are carried along with sensory and efference copy signals by parallel fibers, while the climbing fiber spikes, which are random and infrequent, provide pulses that serve to synchronize the learning process. The unique feature of InMin is that it uses total parallel fiber input as a negative reinforcement signal and it learns to reduce both the error and the effort associated with any input–output transformation by minimizing its total parallel fiber input (hence the name). InMin successfully trains neural system models to simulate the kinds of motor control exhibited by the real cerebellum, and the neural elements representing Purkinje cells in trained models have properties that resemble those of real Purkinje cells.

Detailed Description

The Marr/Albus Paradigm

In 1969 David Marr published a highly influential paper describing a model of cerebellar learning (Marr 1969). This model was elaborated by James Albus (Albus 1971), and ever since the Marr/Albus paradigm has provided the framework for almost all models of learning in the cerebellum. Although the cerebellum is involved in many neurological processes, it is most closely associated with motor control, and because eye movements can be studied relatively easily and precisely, many neural systems models of cerebellar learning have been considered in the context of adaptive oculomotor control. Almost all of these models are based on the Marr/Albus paradigm (e.g., Fujita 1982; Ito 2000; Yamamoto et al. 2002). Input minimization (InMin) represents a departure from this tradition.

The Marr/Albus paradigm treats cerebellar learning as perceptron learning. In this framework, the weights of the connections from parallel fibers onto Purkinje cells are trained in a supervised, error-driven fashion using precise error signals provided to Purkinje cells by climbing fibers. This is an elegant and effective scheme, but the evidence that climbing fibers carry error signals is inconclusive (Gibson et al. 2004; Kitazawa and Wolpert 2005). Climbing fibers fire spikes at a low average rate of about 1 Hz; modulations of this low rate are difficult to discern and the interspike intervals are random (Keating and Thach 1995). Available data certainly leave open the possibility that the climbing fiber input to Purkinje cells serves a purpose other than error signaling.

InMin Models of Cerebellar Function

InMin is used to train neural system models that are based on the neuroanatomy of the cerebellum (Eccles et al. 1967; Llinás and Walton 1990). A generic scheme for modeling cerebellar adaptation of motor control is shown in Fig. 1. In this scheme, Purkinje and stellate cells are modeled as

Modeling Cerebellar Learning: Input Minimization, Fig. 1 Schematic diagram of the input minimization (InMin) model of cerebellar learning

summing units while granule cells and climbing fibers are binary (for clarity of description, all units are referred to using the names of the actual cell types they represent). Purkinje cells receive excitatory input from parallel and climbing fibers and inhibitory input from stellate cells. Each parallel fiber arises from a separate granule cell. Subsets of granule cells receive the same mossy fiber, and each mossy fiber carries a differently phase-shifted version of the input. Phase dispersion is a characteristic of visual, vestibular, and other oculomotor-related mossy fiber signals (e.g., Miles et al. 1980; Mustari et al. 1988). Mossy fibers encode sensory and efference copy signals. Each granule cell in a subset has its own unique threshold, so each provides its own distinctly phase-shifted and threshold-limited version of the input to Purkinje cells. Depending on the application, granule cells outnumber Purkinje cells by one or two orders of magnitude, and together the mossy fibers and granule cells produce an expansive recoding of the input. InMin is compatible with any sort of expansive recoding of mossy fiber signals at the granular layer, including the nonlinear combinations of the kind used in support vector machines.

Each Purkinje and stellate cell computes the weighted sum of its parallel fiber inputs. Stellate cells inhibit Purkinje cells, and in some InMin applications this is modeled as a shunting inhibition which lowers Purkinje cell sensitivity. The weighted sum of the Purkinje cell responses is then used as a signal to adjust an ongoing sensorimotor process; oculomotor examples include vestibuloocular image stabilization or smooth pursuit tracking. The difference between a desired output and the output of the cerebellar-adjusted process forms an error signal which is delayed, expansively recoded, and presented as additional parallel fiber signals to Purkinje and stellate cells. The climbing fiber produces spikes at random times with an average interspike interval of 1 s. These synchronize learning in the model.

Each climbing fiber spike initiates one cycle of standard self-organizing feature map training (Kohonen 1997). Briefly, the Purkinje cell with the strongest response is determined, and it and its neighbors are made more sensitive to the current pattern of parallel fiber input, by adding a scaled version of the parallel fiber input vector to the parallel-Purkinje weight vectors of the Purkinje cells in the training neighborhood and normalizing. Each climbing fiber spike also initiates one cycle of perturbative reinforcement training, the form of which is based on the directed-drift algorithm (Venkatesh 1993). Briefly, some parameter that determines the magnitude of the Purkinje cell adjustment of the controlled process is transiently perturbed, and the effect of this perturbation on total parallel fiber input is assessed. The assessment is based either on delayed or integrated parallel fiber signals in order to account for the delay inherent in the error-related component of the total parallel fiber signal. Perturbed parameters can include the amount of stellate shunting inhibition or the Purkinje cell output weight, and the perturbation can be applied to a single (generally the most strongly responding) Purkinje cell or to any subset of Purkinje cells. If the total parallel fiber input is decreased by the perturbation, then it is reinstated. Otherwise the parameter is kept at its pre-perturbation value.

InMin has been applied in modeling cerebellar learning in the context of adaptation of the vestibuloocular reflex (Anastasio 2001a) and

smooth pursuit (Rothganger and Anastasio 2009). Retinal error signals are produced whenever either the vestibuloocular or the pursuit systems operate imperfectly, and saccadic eye movements can be triggered during imperfect pursuit to momentarily reduce the error. As stated above, signals such as retinal error and saccade command efference copy are carried by parallel fibers, along with visual, vestibular, and other signals. By minimizing overall parallel fiber input, InMin reduces both retinal error and saccade efference copy signals, making the controlled system more accurate and, in the pursuit case, more efficient.

InMin trains Purkinje cells to act as feedforward pattern correlators that each respond best to a unique pattern of parallel fiber activity and make an adjustment that improves the performance of the controlled system (e.g., vestibuloocular or pursuit). In this regard cerebellar models trained by InMin are similar to Marr/Albus models (see also Anastasio 2001b). However, the properties of the Purkinje cells in InMin models, which resemble those of real Purkinje cells, differ in a critical respect from those in Marr/Albus models. This is illustrated in Fig. 2. Panel A shows simulated eye position following InMin training on a circular pursuit task. Model output closely matches the desired output. Panel B shows the responses of all of the Purkinje cells that control the horizontal component of the movement (those controlling the vertical component are similar). The responses are roughly sinusoidal because the production of a circular 2D trajectory requires sinusoidal horizontal and vertical components. The responses appear jagged because their parallel fiber inputs come from binary granule cells. Crucially, all of these Purkinje cells are from the same model microzone. A microzone is defined as all of the Purkinje cells that are innervated by the same climbing fiber (Oscarsson 1979). Note that all of the Purkinje cell responses in Panel B have distinct phases. The same model was then trained under the Marr/Albus, error-driven learning paradigm. Overall model behavior was very similar to that shown following InMin training in Panel A. The Purkinje cell responses following Marr/Albus training, shown in Panel C, all have the same phase, because they are all correlated with the same error signal as supplied, according to the

Modeling Cerebellar Learning: Input Minimization, Fig. 2 Using InMin to simulate pursuit learning. Panel A shows the output of the model after training on a circular pursuit task. Panel B shows the responses following InMin training of the Purkinje cells controlling the horizontal eye movement component (those controlling the vertical component are similar). Panel C shows the horizontal Purkinje cell responses following Marr/Albus training on the circular pursuit task (model performance following Marr/Albus training was similar to that following InMin training, which is shown in panel A)

Marr/Albus paradigm, by their common climbing fiber. These results stand as a prediction. If the Marr/Albus paradigm is correct, then all Purkinje cells in a microzone following vestibular or pursuit training should have the same phase. If they are not, then an alternative account, such as InMin, should be considered instead.

Definition

Realistic models for ionic concentration changes should capture essential aspects of ionic dynamics which are relevant for neuronal function. Ionic concentration changes affect many ionic channels and thereby also the membrane voltage. In addition, ionic concentration changes (e.g., calcium concentration changes) influence also intracellular biochemical signaling cascades. Ionic dynamics is an important determinant of neuronal inhibition, excitability, and synaptic plasticity. We will first introduce how to model intracellular ionic dynamics in general and then describe briefly some details relevant for modeling calcium and chloride dynamics.

Detailed Description

Ion Influx

Ions enter the neuron via ion channels in the cell membrane. This influx can be modeled as a **linear ohmic current**:

$$I_{\text{ion}} = g_{\text{ion}} (V - E_{\text{ion}})$$

where V is the membrane potential, g_{ion} is the membrane ionic conductance (which can be voltage or ligand gated), and E_{ion} is the reversal potential which is given by the **Nernst equation**. However, if ionic currents are rectifying and show strong deviations from ohmic behavior (as in the case of calcium currents), one should use a more accurate **nonlinear** formalism such as the **Goldman–Hodgkin–Katz equation** (GHK):

$$I_{\text{ion}} = P_{\text{ion}} z^2 F^2 V / RT \frac{[\text{Ion}]_i - [\text{Ion}]_o \exp(-zFV/RT)}{1 - \exp(-zFV/RT)}$$

where P_{ion} is the total ion permeability, z is the valence of the ion, F is the Faraday constant, V is the membrane voltage, R is the gas constant, T is the absolute temperature, and $[\text{Ion}]_o$ and $[\text{Ion}]_i$ are the extra- and intracellular ion concentrations, respectively. To calculate the total ion permeability, one can multiply the maximum ion permeability by the time-varying fraction of open channels (e.g., given by Hodgkin–Huxley-like gating variables). The contribution of the ion influx (I_{ion}) to the ion concentration change inside a cellular compartment can be calculated as follows:

$$\frac{d[\text{Ion}]_i}{dt} = -\frac{I_{\text{ion}}}{zF\text{volume}}$$

where z is the valence of the ion, F is the Faraday constant, volume is the volume into which the ions flow, and t is time.

Ion Removal

Ions can be removed by various pumps and exchangers which are present on the cell

membrane and on the membrane of intracellular organelles. These ion removal mechanisms can be represented by simple **phenomenological** models with low number of parameters or by complex **biophysical** models including many buffers and pumps. A commonly used phenomenological model of ion influx and removal is the **exponentially decaying pool model** of ion concentration:

$$\frac{d[\text{Ion}]_i}{dt} = -\frac{I_{\text{ion}}}{zF\text{volume}} + \frac{[\text{Ion}]_i^{\text{rest}} - [\text{Ion}]_i}{\tau_{\text{ion}}}$$

The equation represents ion accumulation due to ion influx (see previous equation) with exponential recovery (decay time constant τ_{ion}) to the resting level of intracellular ion concentration $[\text{Ion}]_i^{\text{rest}}$. The decay time constant determines the ion removal rate and approximates the removal effects of buffers and pumps. If the simplification of the ion removal to a single time constant is not sufficient to capture observed ion dynamics, one should use more realistic biophysical models of ion transport and buffering. A simple **biophysical** model for ion removal mediated by a pump is a **Hill equation**:

$$\frac{d[\text{Ion}]_i}{dt} = -v_{\text{max}} \frac{[\text{Ion}]_i^n}{K_d + [\text{Ion}]_i^n}$$

where v_{max} is the maximum rate of ion transport, K_d is the dissociation constant (neuronal $[\text{Ion}]_i$ at which the extrusion rate is half maximal), and n is the Hill coefficient (describes the cooperativity of ion binding). If $n = 1$ (noncooperative ion binding), the Hill equation reduces to **Michaelis-Menten kinetics**. This pump model represents an outward transport mechanism and may drive intracellular ion concentration below its resting level. Therefore, in practice, a small leak influx (from extracellular space or intracellular organelles) is often included in the model to achieve steady-state resting ion concentration:

$$\frac{d[\text{Ion}]_i}{dt} = -\frac{I_{\text{ion}}}{zF\text{volume}} + \text{leak} - v_{\text{max}} \frac{[\text{Ion}]_i^n}{K_d + [\text{Ion}]_i^n}$$

Ion Diffusion

In neuronal models with multiple compartments, it is often necessary to implement diffusion of ions between compartments and within compartments.

Simplified **one-dimensional diffusion** modeling (De Schutter and Smolen 1998) can be employed if highly local (nano- and micro-domain) ionic changes can be neglected. Ion diffusion can be formalized using **Fick's first law** according to which the net flow of ions (J , i.e., the diffusion flux or the amount of ions per unit time) is equal to the product of the coefficient of diffusion (D_{ion}), the spatial concentration gradient ($d[\text{Ion}]/dx$), and the area across which the ions diffuse (A):

$$J = -D_{\text{ion}} \frac{d[\text{Ion}]}{dx} A$$

The direction of the ionic flux (between compartments or subcompartments) is opposite to the concentration gradient, and thus the gradient gets smaller over time. **Longitudinal diffusion** (along the length of the dendrite) can be modeled in one dimension as an exchange of ions between adjacent compartments described by the Fick's law. For one-dimensional **radial diffusion** (perpendicular to the axis of the dendrite), the volume of a single compartment can be discretized into a series of **concentric shells** around a cylindrical core (De Schutter and Smolen 1998). Again, the ion flux between neighboring shells can be described by the Fick's law: $-D_{\text{ion}} \Delta[\text{Ion}]/\Delta r A$, where D_{ion} is the diffusion coefficient, $\Delta[\text{Ion}]$ is the concentration difference between shells, Δr is the distance between the shell centers, and A is the area of the boundary between neighboring shells (Hines and Carnevale 2000).

One-dimensional diffusion models are computationally fast. However, for the realistic modeling of highly local ionic dynamics, full **three-dimensional diffusion models** including stochastic diffusion might be necessary (for details, see Smith 2001; Bhalla and Wils 2010; De Schutter 2010). Furthermore, using "pure" (Fickian) diffusion to model ionic dynamics assumes that ionic movement is driven to a much larger extent by concentration gradients than by electrical

potential gradients. This simplification can be removed by using the **Nernst–Planck electrodiffusion equation** (e.g., Qian and Sejnowski 1989; Lopreore et al. 2008). It is a matter of current debate under which physiologically relevant conditions the electrodiffusion equation is more accurate than the classical cable equation combined with “pure” diffusion equations (De Schutter and Smolen 1998; De Schutter 2010; see also entry ► “Diffusion Equation” and the references therein). Recent computer modeling showed that large-scale diffusion of charged ions in extracellular space is able to affect local field potentials (Halmes et al. 2016, 2017). These simulations were based on an electrodiffusive (Kirchhoff–Nernst–Planck) formalism (Halmes et al. 2016).

Modeling Intracellular Calcium Dynamics

Calcium modeling is very often used in neuronal models. The reason is that neuronal electrical activity depends on multiple calcium-gated channels and also many other important neuronal phenomena (e.g., synaptic plasticity) are calcium dependent. The details of calcium modeling approaches can be found in several reviews (e.g., De Schutter and Smolen 1998; Smith 2001; Holcman et al. 2005; De Schutter 2010; Blackwell 2013; see also Chap. 6 in Sterrat et al. 2011). Briefly, **calcium influx**, **calcium removal**, and **calcium diffusion** can be modeled using general approaches for simulating ionic dynamics which we described above. **Calcium buffering** can be formalized using the following kinetic reaction for the interaction between calcium (Ca^{2+}) and a buffer B:

where $[\text{B}]$ and $[\text{CaB}]$ are free and bound buffer concentration, respectively, and kf and kb are the rate constants for the forward and backward reactions, respectively (De Schutter 2010). Most buffers are mobile and therefore their diffusion should be also included in calcium buffering models. Thus, four parameters are needed to fully characterize each buffer: kf , kb , diffusion coefficient, and total buffer concentration

(De Schutter 2010). In some cases (e.g., in models of synaptic plasticity), **calcium release** from internal stores (endoplasmic reticulum) needs to be simulated (Jedlicka and Deller 2017). Calcium release (through IP3 receptors or through ryanodine receptors) can be modeled as a gated flux along the concentration gradient:

$$\frac{d[\text{Ca}^{2+}]_i}{dt} = V_R f_0 \left([\text{Ca}^{2+}]_s - [\text{Ca}^{2+}]_i \right)$$

with V_R as the maximum rate of release, f_0 as the fraction of open channels, and $[\text{Ca}^{2+}]_s$ as the calcium concentration in the stores (De Schutter 2010). The Hill function (see above) can be used to compute f_0 from ligand concentrations (e.g., IP3 and calcium are ligands for the IP3 receptors).

The choice of the best approach to modeling calcium depends on the properties of the phenomenon that one wants to simulate. For detailed guidelines on how to choose the proper level of simplification in the calcium model, see De Schutter (2010). In compartmental models, it is often sufficient to compute calcium concentration only in the submembrane region to activate calcium-dependent channels in the cell membrane. In such case, the **exponentially decaying calcium model** (see above) can be used to implement calcium influx and removal. In this simple phenomenological model, the calcium influx contributes to calcium concentration changes only in a thin **submembrane shell** with small volume and thus can be used to open a calcium-activated (e.g., potassium BK) channel. If multiple calcium-dependent channel types or other calcium-dependent mechanisms need to be used in a compartment model, then biophysical models for calcium buffers and pumps should be included. Realistic modeling of highly local calcium concentration changes in **micro-** or **nano-domains** usually requires highly detailed three-dimensional morphology models; detailed biophysical models of calcium channels, pumps, and buffers; and determinist or stochastic **three-dimensional reaction–diffusion** modeling approaches (e.g., voxel-based **finite-volume** methods or **continuous random walk/ Monte Carlo** methods; Stiles and Bartol 2001; Bhalla and Wils 2010).

Modeling Intracellular Chloride Dynamics

Although chloride plays a crucial role in synaptic transmission and neuronal excitability (De Koninck 2007), so far, chloride modeling has not been extensively used in computational neuroscience. In fact, most models keep chloride concentration constant in spite of experimental evidence that it can change rapidly. Only recently, computational models for chloride influx, removal, and diffusion in large neuronal morphologies became available (Jedlicka et al. 2011; Doyon et al. 2011; Lewin et al. 2012; Mohapatra et al. 2016). These models were used to study activity-dependent changes of intracellular chloride concentration and their impact on synaptic inhibition. Similar to calcium, **chloride influx**, **chloride removal**, and **chloride diffusion** can be modeled using general approaches for simulating ionic dynamics which we described above. An important difference to calcium modeling is that **chloride buffering** can be neglected since chloride is thought to diffuse freely (Kuner and Augustine 2000). Chloride extrusion can be approximated by the exponentially decaying chloride model (Jedlicka et al. 2011). If complex interactions of chloride with other ion species (e.g., K^+ , Na^+ , H^+) need to be simulated, detailed biophysical models for chloride pumps and transporters such as K^+/Cl^- cotransporter (KCC2), $Na^+/K^+/Cl^-$ cotransporter (NKCC1), or Cl^-/HCO_3^- exchanger should be used as described in Doyon et al. (2011) and Lewin et al. (2012). Notice that current chloride dynamics models use determinist one-dimensional diffusion (Jedlicka et al. 2011; Lewin et al. 2012) or electrodiffusion (Doyon et al. 2011). Thus, they neglect potential effects of stochastic three-dimensional chloride diffusion. It remains to be tested whether three-dimensional diffusion or electrodiffusion (Lopreore et al. 2008) is needed for correct simulations of highly local chloride changes. Recent stochastic simulations showed that dendritic spines were able to slow down longitudinal chloride diffusion along dendrites (Mohapatra et al. 2016). Such effects may alter short-term ionic plasticity of inhibitory synapses (Mohapatra et al. 2016). However, since similar results were observed also in deterministic simulations,

potential advantages of stochastic three-dimensional diffusion or electrodiffusion still need to be explored.

Definition

Within the gastrointestinal (GI) tract, the stomach generates and propagates an omnipresent rhythmic electrical activity known as the gastric slow-wave. The interstitial cells of Cajal (ICCs) are now widely regarded as the pacemaker cells that generate the slow waves that propagate to neighboring ICCs and smooth muscle cells (SMC). Thus, a multicellular network of ICC and SMC can represent the behavior of slow waves in the stomach.

Detailed Description

Essential Anatomy

The human stomach is divided into three central regions; the rostral region is called the fundus, the caudal region is the antrum, and the region in between is known as the corpus (Mandal et al. 2016). The junction between the stomach and the small intestine is known as the pylorus (Fig. 1a). The stomach wall consists of different layers from outside to inside (Fig. 1b). The outermost layer is serosal. Two muscle layers are underneath it: a longitudinal muscle layer and a circular muscle layer. A neural layer called the myenteric plexus resides between these two muscle layers. Two main types of ICC have been identified in the stomach (Camborová et al. 2003). There is a dense cellular network of pacemaker ICC in the myenteric plexus (ICC_MY), whereas intramuscular ICCs (ICC_IM) are interspersed between muscle cells, mainly in the circular layer, from the oral end (fundus) to the anal end (antrum) of the stomach.

Modeling of Slow Waves in the Stomach, Fig. 1 (a) Anatomy of the stomach based on Mandal et al. 2016. (b) Schematic representation of different layers in the gut based on Camborová et al. 2003

Slow Waves in the Stomach

Slow waves originate from dominant pacemaker ICCs within the stomach wall along the greater curvature in the mid-corpus and spread aborally through the antrum to the pyloric sphincter. Although, the ICC_MY are widely believed to be responsible for the regular electrical slow-wave activity in the stomach (Hirst and Edwards 2001); ICC_IM may also play a role (Hirst et al. 2006). There have been substantial efforts to understand the generation and propagation of the slow-wave and the change in slow-wave characteristics in a dysfunctional stomach. Despite these efforts, the physiology behind the aberrant slow-wave in a dysfunctional stomach is not understood. There have been several efforts to simulate the slow waves in a multicellular model of the stomach. Since ICC may be responsible for the generation and propagation of slow waves, and slow-wave recordings are usually obtained from SMC, computational models of these two layers of cells can be used to analyze aspects of the functional behavior of the stomach. Modeling of single ICC and single SMC has been done by various groups (Youm et al. 2006; Corrias and Buist 2007, 2008; Faville et al. 2009; Du et al. 2010; Lees-Green et al. 2014), and this effort offers a basis for multicellular modeling of the slow-wave in the stomach.

Models of Single ICC

Several computational models for a single ICC of the GI tract (consisting of the stomach, small

intestine, and colon) have been developed. In a single cell model of an intestinal ICC, the role of several ion channels that are believed to participate in the generation and development of the slow-wave have been described (Youm et al. 2006). The model includes an inward rectifier K^+ current (I_K), an L-type Ca^{2+} current (I_{L-type}), a voltage-dependent and dihydropyridine-resistant Ca^{2+} current (I_{VDDR}), an autonomous inward current (I_{AI}), a Na^+/Ca^{2+} pump current (I_{NaCa}), a Na^+/K^+ pump current (I_{NaK}), and a plasmalemmal Ca^{2+} pump current (I_{PMCA}). Time-dependent change in the membrane potential is described by the following equation:

$$\frac{dV}{dt} = \frac{-(I_{tot} + I_{ext})}{C_m}, \quad (1)$$

where I_{ext} is the external current applied, C_m is the cell membrane capacitance, and

$$I_{tot} = I_K + I_{CaL} + I_{VDDR} + I_{AI} + I_{NaCa} + I_{NaK} + I_{PMCA}, \quad (2)$$

$$I_K = G_K \left(\frac{[K^+]_0}{5.4} \right)^{0.62} (V - E_K) n f_U, \quad (2.1)$$

$$I_{CaL} = P_{CaL} Ca_{CF} m h, \quad (2.2)$$

$$I_{VDDR} = P_{VDDR} Ca_{CF} m h, \quad (2.3)$$

$$I_{AI} = P_{AI}(Ca_{CF} + 0.36K_{CF} + 0.4Na_{CF})p(AI), \quad (2.4)$$

$$I_{NaCa} = P_{NaCa}(k_1p(E_1Na)y - k_2p(E_2Na)(1 - y)), \quad (2.5)$$

$$I_{NaK} = \frac{P_{NaK}}{1 + \left(\frac{Km_{Na}}{[Na^+]_i}\right)^{1.36}} \frac{1 - ((V + 50)/250)^2}{1 + \frac{Km_{Ko}}{[K^+]_o}}, \quad (2.6)$$

$$I_{PMCA} = \frac{P_{PMCA}}{1 + \left(\frac{Km_{Cai}}{[Ca^{2+}]_i}\right)^2}, \quad (2.7)$$

where G_X denotes conductance of ion channel X, E_X denotes reversal potential of ion channel X, $[X]_o$ denotes the extracellular concentration of ion X, $[X]_i$ denotes the intracellular concentration of ion X, f_U denotes the fraction of unblocked channels, P_X denotes conversion factor for ion channel X, X_{CF} denotes constant field equation of ion channel X, m and n denote activation gate variable, h denotes inactivation gate variable, p (X) denotes the probability of state X, and y denotes gate variable in the reduced two-state model (Powell et al. 1993). Km_{Na} , Km_{Ko} , and Km_{Cai} are empirical constants.

In this model, the L-type Ca^{2+} channel in an ICC supposedly activates in response to the depolarization of the previous ICC. However, the channel is represented by a two-state model for the single ICC. The K^+ current repolarizes the pacemaker potential, the I_{VDDR} contributes to slow-wave propagation in the GI tract, the I_{AI} works as the pacemaker current generating the spontaneous depolarization of ICC without an electrical stimulus, the Na^+/Ca^{2+} pump extrudes single calcium ion in exchange for three sodium ions, the Na^+/K^+ pump extrudes three Na^+ ions in exchange for two K^+ ions generating a net outward current. The model also includes inositol 1,4,5-trisphosphate (IP_3) production and IP_3 -mediated Ca^{2+} release activity from the endoplasmic reticulum (ER). The model produces a spontaneous slow-wave whose frequency is 20 cycles per minute (cpm), and resting potential is -78 mV, which are close

to in vitro recordings from the murine small intestine (Goto et al. 2004). However, the role of the mitochondria in the generation of the slow-wave is not taken into account despite experimental evidence of the cessation of slow waves under the presence of mitochondrial uncouplers and inhibitors of the mitochondrial Na^+/Ca^{2+} exchanger (Magnus and Keizer 1997).

Another biophysical model of the single ICC was developed by Corrias and Buist for the stomach (Corrias and Buist 2008). This model is based on the hypothesis that Ca^{2+} shuttling between mitochondria and ER is responsible for the pace-making capabilities of ICC. The model includes several ion channel currents such as the I_{VDDR} and I_{L-type} , voltage-dependent K^+ channel (encoded by the $Kv1.1$ gene) current ($I_{kv1.1}$), Ether-a-go-go (ERG) K^+ channel current (I_{ERG}), calcium-dependent K^+ current (I_{CaK}) and background K^+ current (I_{kb}), a Na^+ channel current (I_{Na}), a chloride channel current (I_{Cl}), and a nonselective cation channel current (I_{NSCC}). The change in membrane potential is given by the following equation:

$$\frac{dV}{dt} = \frac{-I_{ion}}{C_m}, \quad (3)$$

where

$$I_{ion} = I_{VDDR} + I_{L-type} + I_{kv1.1} + I_{ERG} + I_{CaK} + I_{kb} + I_{Na} + I_{Cl} + I_{NSCC}, \quad (4)$$

$$I_{VDDR} = G_{VDDR}d_{VDDR}f_{VDDR}(V - E_{Ca}), \quad (4.1)$$

$$I_{L-type} = G_{L-type}d_{L-type}f_{L-type}f_{Ca}(V - E_{Ca}), \quad (4.2)$$

$$I_{kv1.1} = G_{kv1.1}d_{kv1.1}f_{kv1.1}(V - E_K), \quad (4.3)$$

$$I_{ERG} = G_{ERG}d_{ERG}(V - E_K), \quad (4.4)$$

$$I_{CaK} = G_{CaK}P_{CaK}(V - E_K), \quad (4.5)$$

$$I_{kb} = G_{kb}(V - E_K), \quad (4.6)$$

$$I_{Na} = G_{Na}d_{Na}f_{Na}(V - E_{Na}), \quad (4.7)$$

$$I_{Cl} = G_{Cl}d_{Cl}(V - E_{Cl}), \quad (4.8)$$

$$I_{NSCC} = G_{NSCC}P_{NSCC}(V - E_{NSCC}), \quad (4.9)$$

where G_X represents conductance of ion channel X, d_X and f_X represent activation and inactivation gating variables for ion channel X, f_{Ca} represents Ca^{2+} -dependent inactivation, E_X represents the Nernst potential of ion X, and P_X represents the open probability of ion channel X.

Here the nonselective cation channels (NSCC) are the primary pacemaker channels that allow ionic flux into the submembrane space between mitochondria and ER. Along with I_{NSCC} , the I_{VDDR} and I_{Na} contribute to the upstroke phase of the slow-wave. The I_{L-type} current is primarily responsible for the plateau phase of the slow-wave. The K^+ channel currents contribute to the down-stroke phase of the slow-wave. The model generates slow waves from a single ICC (Fig. 2) whose pacemaking frequency is 3.02 cpm, and resting potential is -67.6 mV, both of which are in agreement with recordings from the ICC of the guinea-pig gastric antrum in an in vitro preparation (Hirst and Edwards 2001).

Peng Du et al. (2010) modified the Corrias and Buist model for the single ICC by addition of a voltage-dependent, IP_3 -related mechanism based on previously published equations (Imtiaz et al. 2002):

Modeling of Slow Waves in the Stomach, Fig. 2 Different phases of the membrane potential of an ICC simulated using the Corrias and Buist (2008)

$$\begin{aligned} \frac{d[IP_3]}{dt} = & \beta - \eta[IP_3] - V_{m4} \frac{[IP_3]^4}{k_4^4 + [IP_3]^4} \\ & + P_{MV} \left(1 - \frac{V_m^8}{k_v^8 + V_m^8} \right), \end{aligned} \quad (5)$$

where β is an external stimulus, η is the rate constant for linear IP_3 degradation, V_{m4} is maximal value for the nonlinear IP_3 degradation, K_4 is half-saturation constant for the nonlinear IP_3 degradation, P_{MV} is maximal rate of voltage-dependent IP_3 synthesis, and K_v is half-saturation constant for voltage-dependent IP_3 synthesis. Voltage-induced IP_3 synthesis is suggested responsible for slow-wave entrainment (Du et al. 2010). The outward current flux from ER depends on IP_3 concentration, which eventually determines the shuttling interval of Ca^{2+} between ER and mitochondria, that is, the frequency of the slow-wave.

While the Corrias and Buist model for the single ICC does not produce any phase change in response to an external current stimulus, the Peng Du model responds to pulse stimuli by phase advancing the intrinsic activity of the ICC while maintaining the same intrinsic frequency. The Peng Du model is thus capable of altering the slow-wave in response to an extracellular current input. Another model of the single ICC was developed incorporating the same mechanisms for the generation of the slow-wave as in the Corrias and Buist model (Faville et al. 2009). The primary difference is that in the Faville model, multiple pacemaker units are incorporated in a single intestinal ICC, and the I_{L-type} current is omitted. The model produces slow-wave depolarizations with an amplitude of 65 mV at a frequency of 17.4 cpm, matching with in vitro recordings from the myenteric ICC of the guinea-pig small intestine (Kito and Suzuki 2003).

Still another model for small intestinal ICC features the calcium-activated chloride channel, anoctamin1 (Lees-Green et al. 2014). This model assumes a store-operated calcium (SOC) channel that responds to the depletion of calcium levels in the ER. Anoctamin1 channels co-localized with

SOC channels are activated by the local rise in Ca^{2+} in microdomains, resulting in depolarization of the ICC. Other than the calcium-activated chloride current (I_{CaCl}), the model includes a T-type Ca^{2+} current (I_{CaT}), background Na^+ current (I_{Na}), I_{Kb} , and voltage or Ca^{2+} -activated non-selective currents or Na^+ current (I_{X}). The change in membrane potential is expressed by Eq. (3), whereas

$$I_{\text{ion}} = I_{\text{SOC}} + I_{\text{CaCl}} + I_{\text{CaT}} + I_{\text{Kb}} + I_{\text{Na}} + I_{\text{X}}, \quad (6)$$

$$I_{\text{SOC}} = G_{\text{SOC}} O_{\text{SOC}} (V - E_{\text{Ca}}), \quad (6.1)$$

$$I_{\text{CaCl}} = G_{\text{CaCl}} O_{\text{CaCl}} (V - E_{\text{Cl}}), \quad (6.2)$$

$$I_{\text{Na}} = G_{\text{Na}} (V - E_{\text{Na}}). \quad (6.3)$$

Here, O_{X} represents the open probability of ion channel X, and as before, G_{X} represents conductance of ion channel X, and E_{X} represents the Nernst potential of ion X. The I_{CaT} is modeled using the I_{VDDR} model from Corrias and Buist (2008), and I_{Kb} is modeled using Eq. (4.6). The I_{CaCl} acts as the pacemaker current. Voltage or Ca^{2+} -activated nonselective channels or Na^+ channels are plausible candidates for generating the plateau current. Although the model simulates the voltage-clamp experiments done earlier (Xiao et al. 2011), and the expression for anoctamin1 has been observed experimentally (Hwang et al. 2009), the type of SOC channel that might be present in the ICC is yet unknown.

Models of Single SMC

Unlike the multiple computational models available for the single ICC, there are relatively few computational models for a single smooth muscle cell of the GI tract. One attempt was made by the same group that modeled the ICC biophysically (Corrias and Buist 2007). The model for the single SMC lacks the pacemaking mechanism like the ICC. The depolarizations are, however, due to several ion channel currents and a stimulus current supplied by the ICC network. The ion channel currents described in the model are: $I_{\text{L-type}}$, low voltage-activated calcium current (I_{LVA}), delayed

rectifier potassium channel current (I_{Kr}), A-type potassium channel current (I_{KA}), calcium-activated potassium current (I_{CaK}), I_{kb} , I_{Na} , and I_{NSCC} . The rate change in the membrane potential of SMC is given by the following equation:

$$\frac{dV}{dt} = \frac{-(I_{\text{ion}} + I_{\text{stim}})}{C_{\text{m}}}, \quad (7)$$

where I_{stim} is the incoming current from ICC, C_{m} is SMC capacitance, and

$$I_{\text{ion}} = I_{\text{L-type}} + I_{\text{LVA}} + I_{\text{Kr}} + I_{\text{KA}} + I_{\text{CaK}} + I_{\text{kb}} + I_{\text{Na}} + I_{\text{NSCC}}, \quad (8)$$

The equations for $I_{\text{L-type}}$, I_{CaK} , I_{kb} , and I_{Na} are the same as Eqs. (4.2), (4.5), (4.6), and (4.7). The equations for other ion channel currents are as follows:

$$I_{\text{LVA}} = G_{\text{LVA}} d_{\text{LVA}} f_{\text{LVA}} (V - E_{\text{Ca}}), \quad (8.1)$$

$$I_{\text{Kr}} = G_{\text{Kr}} x_{r1} x_{r2} (V - E_{\text{K}}), \quad (8.2)$$

$$I_{\text{KA}} = G_{\text{KA}} x_{A1} x_{A2} (V - E_{\text{K}}), \quad (8.3)$$

$$I_{\text{NSCC}} = G_{\text{NSCC}} m_{\text{NSCC}} r_{\text{lig}} h_{\text{Ca}} (V - E_{\text{NSCC}}). \quad (8.4)$$

As before, G_{X} represents conductance of ion channel X, d_{X} and f_{X} represent activation and inactivation gating variables for ion channel X, and E_{X} represents the Nernst potential of ion X. Other than that, x_{r1} and x_{A1} are Hodgkin-Huxley type activation gating variables for delayed rectifier and A-type potassium channels, x_{r2} and x_{A2} are Hodgkin-Huxley type inactivation gating variables for the respective potassium channels, m_{NSCC} represents the voltage dependency of the activation kinetics of the NSCC channel, r_{lig} represents the fact that NSCC channels are activated by muscarinic ligands, and h_{Ca} facilitates the effect that intracellular Ca^{2+} has on I_{NSCC} .

A phenomenological description of intracellular Ca^{2+} dynamics is included because of its primary importance in regulating several cellular

processes. In terms of shape, duration, and amplitude, the resulting simulated smooth muscle depolarizations are in good agreement with in vitro recordings from the canine antrum SMC in control and altered (while ion channels are blocked) conditions (Ward et al. 2004).

The Corrias and Buist model for the SMC was used to simulate the response of rat smooth muscle cells to electrical stimuli (Du et al. 2009). Computational models for smooth muscle cells of the small intestine (Poh et al. 2012) and colon (Yeoh et al. 2017) have also been published.

Models of a Multicellular Network of the GI Tract

There have been several approaches to model slow waves using a multicellular network of the GI tract. Some have employed continuum field models, while others have employed explicit multicellular models. A continuum nonlinear dual cable model is notable where the ICCs and SMC are spatially distributed (Buist et al. 2010). The distribution is described by the following equations:

$$\sigma_{ICC} \frac{\partial^2 V_{(ICC)}}{\partial x^2} = A_{m(ICC)} \left(C_{m(ICC)} \frac{\partial V_{(ICC)}}{\partial t} + (I_{ion(ICC)} - I_{coup}) \right), \quad (9)$$

$$\sigma_{SMC} \frac{\partial^2 V_{(SMC)}}{\partial x^2} = A_{m(SMC)} \left(C_{m(SMC)} \frac{\partial V_{(SMC)}}{\partial t} + (I_{ion(SMC)} + I_{coup}) \right), \quad (10)$$

$$I_{coup} = g_{coup} \eta_{ICC} (V_{(ICC)} - V_{(SMC)}). \quad (11)$$

Here, with the appropriate subscripts differentiating ICC and SMC parameters, V , C_m , and I_{ion} represent the definitions provided earlier in the “Models of Single ICC” section, σ is the axial conductivity, x is a spatial coordinate along the axis of the fiber, A_m is the surface-to-volume ratio, and g_{coup} is the electrical conductance between ICC and SMC.

The result was a 337 mm long cable discretized at a 1-mm resolution representing a stomach from the fundus to the antrum. A linear IP_3 concentration gradient is included in the model to yield an entrained pacing frequency of 3.1 cpm across the

length of the model which matches with the in vitro recordings from smooth muscle cells of the guinea-pig antrum (Hirst and Edwards 2001), but does not match with the in vitro recordings from smooth muscle cells of the guinea-pig corpus (Hirst et al. 2006). Additionally, the model includes a hypothesized ionic channel current formulated by directing a small percentage of the whole-cell voltage-dependent dihydropyridine-resistant current into the aggregate ICC pacemaker submembrane space in order to reproduce entrainment. The existence of this channel current has not yet been verified experimentally.

Among the multicellular models, some have been phenomenological, whereas others have been biophysical with a detailed description of ion channels and intra- and intercellular mechanisms. A phenomenological model simulates the intestinal slow-wave (Aliev et al. 2000) using a one-dimensional array of 300 coupled cells. The model conceptually distinguishes slow waves as two interconnected electrical events generated from the ICCs and a longitudinal muscle layer. The primary expression of the model comprises two first-order ordinary differential equations to describe the electrical activity in each tissue layer:

$$u_t = ku(u - a)(1 - u)v + D_{ii/l} \nabla_u^2 + \alpha D_{ii}(u_l - u_i), \quad (12)$$

$$v_t = \varepsilon(\gamma(u - \beta) - v), \quad (13)$$

where u and v stand for the transmembrane potential and slow currents, respectively, u_t and v_t are their first derivatives with respect to time, ε is proportional to the frequency of oscillations in the ICC layer, α describes the symmetry of coupling between the two layers, and D represents the coupling coefficient with subscripts i and l which stand for ICC and longitudinal muscle cell, respectively. The parameters used in these equations are adjusted to fit the model's output to experimental data (Sarna et al. 1971). This model can reproduce the basic properties of electrical activity in the intestine such as the spatial variation of the frequency of oscillation along the gut (19.7 cpm proximally and 17.8 cpm distally), synchronization across short distances and

desynchronization across long distances, and a reduction in propagation length and time toward the distal part. However, the frequency becomes irregular toward the distal part and the membrane potential shapes are deformed compared to those measured in the canine intestine in vitro (Sarna et al. 1971).

An electrical phenomenological description of the generation and propagation of slow waves was provided for the guinea-pig gastric antrum (Edwards and Hirst 2006). In this electrical model, three distinct sets of electrical cables (each consisting of series circuits of resistances and source potentials) are linked. One cable is made of chains of longitudinal muscle compartments; a second is made of a chain of ICC_MY, with the third being a chain containing a mixture of circular smooth muscle cells and ICC_IM orientated at right angles to the longitudinal muscle chain. ICC_MY are connected to both muscle layers resistively. Each tissue layer represents a length of 2 mm as a series connection of 20 iso-potential compartments, each 100 μ m long. The values of the communicating conductance between the three compartments were taken from in vitro experiments in the guinea-pig gastric antrum (Cousins et al. 2003). The model reproduces the longitudinal and circumferential propagation of the slow-wave in an in vitro preparation of the guinea-pig gastric antrum. However, the predictive power of the model is limited by the accuracy of the kinetic models used for the primary and plateau components of the pacemaker potential in the myenteric ICC network and the regenerative potential in circular muscle compartments.

Some groups have tried to incorporate a biophysical approach to represent the slow-wave in the stomach. A multicompartment model of the colon comprised of ICCs, SMC, and enteric neurons is one such effort (Barth et al. 2017). The model was designed to recreate peristalsis, where enteric neurons (a network of sensory neurons, motor neurons, and interneurons) integrate sensory feedback to control smooth muscle contraction. Enteric neurons are modeled biophysically as Connor-Stevens neurons where the neurons have a leak channel current (I_{leak}), voltage-gated

sodium current, potassium current, and a transient potassium current (Connor and Stevens 1971). ICCs are modeled phenomenologically as resistive cables (Edwards and Hirst 2006), and smooth muscle cells are defined by a conductance model with ionic membrane currents (I_{leak} , I_K , and I_{CaL}) and synaptic currents. Synaptic currents include excitatory junction potentials (I_{EJP}), inhibitory junction potentials (I_{IJP}), and gap junctions (I_{gap}). The smooth muscle cells in this model are connected to ICCs by gap junctions and motor neurons by neuromuscular junctions. Sensory neurons are connected to local ascending and descending interneurons by excitatory synapses. Ascending interneurons innervate neighboring excitatory circular motor neurons orally, and descending interneurons innervate neighboring inhibitory circular motor neurons anally. The group also assessed rat colon transit time experimentally, and compared the results to the ones from their in silico model. Although the model provides a reasonable estimate of the colonic transit time, its applicability is limited due to its non-biophysical approach of modeling pacemaker cells.

In Peng Du's multicellular model of the stomach (Du et al. 2010), simulations have been conducted over a linear one-dimensional chain of ICCs arranged as a single geometric element of length 2 mm, at 0.2-mm spatial discretization. The equations used in this model to simulate propagation of slow-wave are as following:

$$\nabla \times ((\sigma_i + \sigma_e)\nabla\varphi_e) = -\nabla \times (\sigma_i\nabla V), \quad (14)$$

$$\begin{aligned} &\nabla \times (\sigma_i\nabla V) + \nabla \times (\sigma_i\nabla\varphi_e) \\ &= A_m \left(C_m \frac{\partial V}{\partial t} + I_{ion} \right), \end{aligned} \quad (15)$$

where V and C_m represent the meanings provided earlier, I_{ion} is the same as I_{tot} in Eq. (2), φ_e represents the extracellular potential, and the σ terms represent tissue conductivity tensors, where the subscripts i and e represent the intracellular and extracellular domains, respectively. Although the equations are for a continuum field model, since the model represents a specific number of cells in

a specified space, essentially the equations represent a multicellular model.

A linear gradient of intrinsic frequencies is assigned to the one-dimensional model by varying the chemical stimulus agent parameter linearly over the chain length to obtain an intrinsic frequency gradient between 3.0 and 2.8 cpm. The model has not been extended to intrinsic frequencies higher or lower than the specified range. A 1-D model of 60 mm in length with 1 mm spatial resolution is described in a subsequent manuscript where an intrinsic frequency range of 4.9–4.0 cpm is produced by changing linear degradation of the IP_3 parameter (Du et al. 2014). In another version, a scaling factor is used to reproduce intestinal slow-wave frequencies as high as 15 cpm (Du et al. 2017).

Unlike other models, a model of slow-wave in the guinea-pig gastric pylorus (van Helden and Imtiaz 2003) includes cells not only electrically interconnected by gap junctions but also chemically. The model includes a one-dimensional array of representative pacemaker cells, with each cell considered to have a length of 100 μ m. Along with the electrical current across the resistive gap junctions, Ca^{2+} and IP_3 are considered to traverse between the pacemaker cells. The model assumes the same voltage-dependent IP_3 synthesis mechanism like Peng Du, but unlike Peng Du, the ionic channels in the pacemaker cells are lumped into a Ca^{2+} channel and a leak current channel. The model produces an accurate representation of the emergence of the slow-wave, although the frequency of the simulated slow-wave is not measurable due to a lack of proper scaling.

There has been substantial progress in mathematical modeling of the slow-wave in the stomach. Phenomenological and biophysical both kinds of models simulate a functional stomach's behavior within a limited capacity. However, a comprehensive model would help us understand the stomach in its functional as well as diseased states, in particular the pathologies related to gastric motility such as tachygastritis and delay in gastric emptying or gastroparesis. A comprehensive model would include detailed intracellular mechanisms, intercellular connection

mechanisms through gap junctions, a long enough representation of the stomach, and a comparison of the model simulation results with previously published experimental recordings from different locations of the stomach. A 2-D, perhaps a 3-D network model of the stomach, may realize all these requirements and improve our understanding of the GI tract. This enhanced understanding will enable us to determine the physiological reasons that may underlie aberrant slow waves and their effect on pathological conditions such as functional uncoupling in the stomach prevalent in diabetes mellitus (Jebbink et al. 1994) and other GI diseases such as functional dyspepsia (Lin and Chen 2001).

Modeling Synapses

Jason S. Rothman

Neuroscience, Physiology and Pharmacology,
University College London, London, UK

Definition

Modeling a synapse usually entails a mathematical description of the transformation of a presynaptic action potential into a postsynaptic response, such as an ionic current. The mathematical description is often phenomenological, treating the synapse as a black box that takes the presynaptic action potential as input, and produces as output a change in the postsynaptic membrane; no explicit modeling of the cascade of biophysical events underlying synaptic transmission is implemented. However, that said, modeling a synapse can also entail a more biophysical than phenomenological approach, describing one or more of the biophysical events underlying synaptic transmission. Such biophysical models might describe, for example, the gating of presynaptic voltage-sensitive Ca^{2+} channels, the diffusion of Ca^{2+} within the presynaptic terminal, the binding of Ca^{2+} to buffers and Ca^{2+} sensors such as synaptotagmin, the binding and fusion of synaptic vesicles at an active zone, the diffusion of neurotransmitter across the synaptic cleft, the gating of postsynaptic neurotransmitter receptors, or the movement of neurotransmitter receptors within the postsynaptic membrane. In some instances, modeling a synapse might entail a mathematical description of an electrical synapse (i.e., a gap junction) between the presynaptic and postsynaptic membrane, rather than the more common chemical synapse which uses neurotransmitter to propagate and transform the presynaptic electrical signal.

Detailed Description

Background

Synapses (Bennett 1999; Palay 1956) are specialized connections that allow signals from a presynaptic membrane to be transmitted to a postsynaptic

membrane. The presynaptic signal is usually an action potential, but can be a simple depolarization away from the resting membrane potential, for example, in some somatic sensory neurons. The postsynaptic response is usually an excitatory postsynaptic current (EPSC) or inhibitory postsynaptic current (IPSC), but can also be a nonelectrical response such as the phosphorylation of proteins. Most synapses occur between neurons but can also occur between neurons and muscle cells, also known as the neuromuscular junction.

Synapses are categorized into two main types: electrical and chemical. Electrical synapses create a direct electrical connection between the presynaptic and postsynaptic membrane via interlinking ion channels (connexins) spanning both membranes. Because of the direct connection, electrical synapses are fast and pass signals bidirectionally. Electrical synapses are also known as gap junctions.

Chemical synapses, in contrast, do not create a direct electrical connection between the presynaptic and postsynaptic membrane, but rather use neurotransmitter as a secondary messenger to convey the presynaptic signal. The introduction of a secondary messenger allows a wealth of computational power not readily achieved by a simple electrical synapse, such as various forms of gain control, plasticity, and inhibitory shunting (Abbott and Regehr 2004; Silver 2010). This higher computational power of chemical synapses is reflected in a large diversity of molecular components, including a range of neurotransmitters (glutamate, glycine, GABA, acetylcholine, dopamine, serotonin, etc.), postsynaptic receptors (ionotropic and metabotropic receptors), as well as presynaptic receptors. There is also a large diversity in the structural aspects of chemical synapses, including the number of presynaptic vesicles (the quantal units that store and deliver neurotransmitter), the number and size of active zones and postsynaptic densities, and the number and location of postsynaptic receptors. The structural arrangement of nearby glia can also influence the computational power of chemical synapses by regulating the concentration of extracellular neurotransmitter (Haydon 2001).

Much of what we know about chemical synapses dates back to 1951, when Fatt and Katz (1951) made the first intracellular recordings of the postsynaptic response at the neuromuscular junction. From these intracellular recordings, Fatt and Katz were able to infer how acetylcholine reacts with its receptor to give rise to the postsynaptic end-plate potential. From then on the technique of intracellular recording moved on to synapses of the central nervous system, and some 50 years later our level of understanding of synaptic transmission has greatly unfolded. Today, we know the basics of chemical synaptic transmission can be summarized in the following cascade of events (see Fig. 1a):

- Step 1: An action potential invades the presynaptic terminal and depolarizes the membrane.
- Step 2: The brief depolarization causes voltage-dependent Ca^{2+} channels to open, leading to a transient increase in the intracellular Ca^{2+} concentration, $[\text{Ca}]_i$.
- Step 3: The increase in $[\text{Ca}]_i$ leads to an increase in probability of one or more synaptic vesicles fusing with the presynaptic membrane, thereby releasing neurotransmitter into the synaptic cleft.
- Step 4: The neurotransmitter diffuses across the synaptic cleft.
- Step 5: The neurotransmitter binds to postsynaptic receptors, causing a conformational change in the receptors.
- Step 6: For ionotropic receptors, the conformational change leads to the opening of their internal ion channel, thereby allowing ionic current to flow, producing an EPSC or IPSC. For metabotropic receptors, the conformational change leads to a chain of intracellular reactions that produce some desired end effect, like phosphorylation of an enzyme or upregulation of a particular receptor subunit.

Modeling any one of the steps 1–6 can be challenging. Hodgkin–Huxley-type models

(Hodgkin and Huxley 1952) of the presynaptic membrane (step 1) or the postsynaptic membrane (step 6) can include several types of ionic conductances, including Na^+ , K^+ , Cl^- , and Ca^{2+} , all of which can vary in density and kinetics between different types of neurons. Markov models of Ca^{2+} channel gating (step 2) or neurotransmitter receptor binding (step 5) can entail complicated pathways between open, closed, blocked, and/or desensitized states, with numerous kinetic parameters (Destexhe et al. 1998). Monte Carlo models of Ca^{2+} diffusion in the presynaptic terminal (step 2) or the postsynaptic dendrite or soma (step 5) usually include several types of Ca^{2+} buffers, each having their own diffusion coefficient and binding/unbinding kinetic reaction. As research progresses, these models are often modified to include more and more biophysical realism with increasing complexity. However, with the increased complexity comes an increase in computational costs. For large-scale neural networks, the increased costs can make simulations intractable. Hence, for neural network simulations simple phenomenological models are usually the rule. These phenomenological models might include one or more kinetic reactions that have only two states, for example, a closed and open receptor channels (Fig. 1b) and/or black boxes that lump together two or more of the steps 1–6, where the input–output relationship of each box is described by a simple mathematical equation (Fig. 1c, top). By far the most computationally efficient approach is to lump steps 2–5 into one black box (Fig. 1c, bottom). This approach coincides with a growing wealth of experimental data obtained from voltage-clamp experiments where a presynaptic action potential is triggered by a stimulating electrode (step 1) while the resulting postsynaptic current (step 6) is simultaneously recorded using an intracellular patch pipette. With little effort such experimental data can be manipulated to provide a transform function for the black box shown at the bottom of Fig. 1c. It is this latter approach that is described here. Except for the final section on electrical synapses, the description focuses entirely on chemical synapses; in these sections “synapse” therefore refers to a chemical synapse.

Modeling Synapses, Fig. 1 Modeling synaptic transmission. (a) Cartoon of a chemical synapse between two neurons showing a presynaptic action potential (AP), vesicles filled with neurotransmitter (dark blue circles), empty vesicles (light blue circles), an active zone (thick black line, left) containing vesicle release sites and voltage-activated Ca²⁺ channels (yellow), a postsynaptic density (thick black line, right) containing neurotransmitter receptors (orange), and an excitatory postsynaptic current (EPSC). Gray numbers denote the six basic steps described in the text. (b) Simple kinetic scheme representing the gating of a presynaptic voltage-activated Ca²⁺ channel with forward and

backward rate constants k_1 and k_{-1} (left). The channel is either closed (C) or open (O). A similar kinetic scheme (right) represents the gating of a postsynaptic receptor binding neurotransmitter (T). (c) Black boxes depicting the signal transformation between the presynaptic action potential and EPSC. In one approach, two transfer functions are used in sequence (top). The simplest approach, however, is to use a single transfer function that takes the time of the presynaptic action potential as its input and produces an EPSC in response (bottom); this is the approach described in the text

Modeling Synaptic Currents/Conductances

A synapse is usually simulated within a single postsynaptic compartment on a dendritic tree or the cell body using a simple electrical circuit as

shown in Fig. 2a. In this circuit, the voltage across the membrane (V_m) can be described by the following differential equation:

$$C_m \cdot dV_m/dt = -G_{leak}(V_m - E_{leak}) + \Sigma I_{adj} + \Sigma I_{syn} \tag{1}$$

Modeling Synapses, Fig. 2 Modeling a postsynaptic conductance. **(a)** Simple electric circuit diagram of a neuron's membrane containing a variable postsynaptic conductance (G_{syn}) with reversal potential E_{syn} , a constant leak conductance (G_{leak}) with reversal potential E_{leak} , and a capacitor (C_m). The circuit includes optional currents from adjacent compartments (I_{adj}). The membrane potential (V_m) is measured across C_m . **(b)** Functions often used to describe the time course of G_{syn} (bottom; see $a(t)$ in Eq. 3) include the single-exponential (1-exp, Eq. 4; $\tau_d = 0.3$ ms),

double-exponential (2-exp, Eq. 5; $\tau_r = 0.2$ ms, $\tau_d = 0.3$ ms), multi-exponential (3-exp, Eq. 6; $n = 2$, $\tau_r = 0.2$ ms, $a_1 = 0.9$, $\tau_{d1} = 0.3$ ms, $a_2 = 0.1$, $\tau_{d2} = 2.0$ ms), and the alpha functions (Eq. 7; $\tau_\alpha = 0.3$ ms). Peak amplitudes were normalized to 1. *Top red trace* shows the arrival time of the presynaptic action potential. There was no delay between the action potential and the generation of G_{syn} , but a delay is sometimes added when modeling synapses

where t is time, C_m is the membrane capacitance, I_{adj} is the flow of current from adjacent electrical compartments, and I_{syn} is the synaptic current, the current of interest for modeling synapses. The circuit could also contain voltage-dependent ion currents, such as Na^+ , K^+ , and Ca^{2+} currents, but for simplicity we assume here a purely passive postsynaptic membrane, in which case the resting membrane potential and resistance are primarily determined by the leak reversal potential (E_{leak}) and conductance (G_{leak}).

In Eq. 1, I_{syn} , the postsynaptic current of interest, is generated at the time of a presynaptic action potential and usually takes the form of the following equation:

$$I_{\text{syn}} = G_{\text{syn}}(t, V_m) \cdot (V_m - E_{\text{syn}}) \quad (2)$$

Here, E_{syn} is the reversal potential of the synaptic conductance and determines whether the synapse tends to depolarize the membrane toward the threshold of action potential generation (e.g., when $E_{\text{syn}} = 0$ mV), in which case the synapse is excitatory, or tends to hyperpolarize the membrane away from the threshold of action potential generation (e.g., when $E_{\text{syn}} = -75$ mV), in which case the synapse is inhibitory. G_{syn} is usually zero under resting conditions, but then becomes positive on arrival of a presynaptic action potential. The amplitude of this positive deflection will be a function of time, but can also be a function of V_m . In most synaptic models, the time and voltage dependencies are usually separated into multiple components, such as in the following expression:

$$G_{\text{syn}} = (t, V_m) = G_{\text{max}} \cdot a(t) \cdot b(V_m) \quad (3)$$

where G_{max} determines the maximum conductance, $a(t)$ determines the rise and decay time course, and $b(V_m)$ determines the amount of voltage-dependent nonlinearity of G_{syn} . Both $a(t)$ and $b(V_m)$ are normalized between 0 and 1 so as to allow G_{max} to determine the maximum value of G_{syn} . If the synaptic conductance is tonically active, then $a(t)$ can be omitted from Eq. 3, or if the synaptic conductance is linear with respect to voltage, then $b(V_m)$ can be omitted. Equation 3 can also be expanded to include time-dependent scale factors for synaptic depression and facilitation described further below.

In Eq. 3, the time course of G_{syn} is determined by $a(t)$. Common expressions for $a(t)$ are 1- and 2-exponential functions such as the following (see Fig. 2b):

$$a(t) = \exp(-(t - t_s)/\tau_d) \quad t \geq t_s \quad (4)$$

$$a(t) = [\exp(-(t - t_s)/\tau_d) - \exp(-(t - t_s)/\tau_r)] / a_{\text{norm}} t \geq t_s \quad (5)$$

where t_s is the time of the presynaptic action potential (with perhaps an added delay to simulate the delay between presynaptic action potential and EPSC), τ_r and τ_d are the rise and decay time constants, $a(t) = 0$ for $t < t_s$, and a_{norm} is a normalization factor that ensures the peak amplitude of $a(t)$ equals 1. The advantage of the 1-exponential function is that it contains only 2 free parameters. The disadvantage is that it ignores the finite rise time of the synaptic conductance, rising instantaneously from 0 to 1 at $t = t_s$. Hence, the 2-exponential function is technically better since it contains a finite rise time. Because the decay of synaptic conductances often contains multiple time constants, such as the NMDA (N-methyl-D-aspartic acid) receptor conductance, Eqs. 4 and 5 are sometimes extended to include multiple decay components, possibly using a notation for the time constants such as τ_{d1} , τ_{d2} , τ_{d3} , etc. Still, Eqs. 4 and 5 may be inadequate in describing a synaptic conductance that exhibits sigmoidal activation, such as the fast AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor conductance. In this case, the following multi-exponential function is sometimes used (Bekkers and Stevens 1996):

$$a(t) = [1 - \exp(-(t - t_s)/\tau_r)]^n \cdot [a_1 \cdot \exp(-(t - t_s)/\tau_{d1}) + a_2 \cdot \exp(-(t - t_s)/\tau_{d2}) + \dots] / a_{\text{norm}} \quad t \geq t_s \quad (6)$$

In this equation, the first term in square brackets determines the rise time course; if the power $n > 1$, then the rise time course exhibits sigmoidal activation. The second term in square brackets determines the exponential decay and can contain one or more time constants as is necessary. Again, a_{norm} is a normalization factor that ensures the peak amplitude of $a(t)$ equals 1 and can be computed numerically by computing the product of the expressions in square brackets at high temporal resolution and setting a_{norm} equal to the peak of the resulting waveform. The disadvantage of Eq. 6 is that it is more computationally expensive than Eqs. 4 and 5, which could have a significant impact on the simulation time,

especially when simulating neural networks. Tricks exist, however, to avoid such computational costs, such as using lookup tables. Yet another popular expression for $a(t)$ is the following equation, also known as the alpha function:

$$a(t) = [(t - t_s)/\tau_\alpha] \cdot \exp(1 - (t - t_s)/\tau_\alpha) \quad t \geq t_s \quad (7)$$

where τ_α sets the time of the waveform's peak. While this function is computationally inexpensive to use, since it contains only 2 free parameters, its rise time is constrained to equal its decay time, since $\tau_r = \tau_d = \tau_\alpha$. Hence, the alpha function

adequately describes only those synaptic conductances where $\tau_r \approx \tau_d$.

Excitatory AMPA and NMDA Receptor Currents

The vast majority of excitatory synapses in the brain use glutamate as their transmitter. At these synapses, glutamate is released from the presynaptic membrane into the synaptic cleft. The released glutamate then diffuses across the synaptic cleft and binds to postsynaptic transmembrane receptors which can be either metabotropic (e.g., mGluRs) or ionotropic. The ionotropic receptors are responsible for generating all or most of the EPSC and are therefore the basis of many synaptic models. The most common of these ionotropic receptors are the AMPA receptors (AMPARs), which mediate the fast component of the EPSC, and the NMDA receptors (NMDARs), which mediate a slower component of the EPSC and can also mediate synaptic plasticity as NMDARs pass Ca^{2+} ions. While a biophysical description of AMPARs and NMDARs can be quite challenging, as these receptors exist in multiple states, including open, closed, desensitized, and blocked states, simple phenomenological models have been quite successful in describing the macroscopic current that passes through these receptors. The voltage dependence of the AMPAR current (I_{AMPAR}), for example, can be adequately described by the following simple ohmic relation derived from Eqs. 2 and 3 (see Fig. 3a, red):

$$I_{\text{AMPAR}} = G_{\text{AMPAR}} \cdot a(t) \cdot (V_m - E_{\text{AMPAR}}) \quad (8)$$

where G_{AMPAR} is the peak AMPAR conductance and E_{AMPAR} is the AMPAR current's reversal potential, typically 0 mV. Because the voltage dependence of I_{AMPAR} is primarily linear, $b(V_m)$ is normally omitted from Eq. 8. Depending on the size of the synaptic connection, which may include more than one active zone, the value of G_{AMPAR} can vary widely, from a few pico-siemens at small bouton synapses to tens of

Modeling Synapses, Fig. 3 Modeling AMPAR and NMDAR currents. (a) Current versus voltage (IV) relation (bottom) of the peak I_{AMPAR} and I_{NMDAR} . Traces at top show overlaid examples of simulated I_{AMPAR} and I_{NMDAR} computed via Eqs. 8 and 9 for holding potentials -100 to $+60$ mV, shifted in time to match the voltage scale of the IV relation (arrows). (b) Boltzmann function describing Mg^{2+} unblock of the NMDAR as a function of voltage (Eq. 10; $V_{0.5} = -12.8$ mV, $k = 22.4$ mV) used to compute I_{NMDAR} in (a)

nano-siemens at large calyx-type synapses. The value of G_{AMPAR} will also vary with temperature. Expressions used to describe $a(t)$ include those defined in Eqs. 4, 5, 6, and 7. Sometimes there are additional slow components of $a(t)$ due to extrasynaptic receptors.

Similar to I_{AMPAR} , the voltage dependence of the NMDAR current (I_{NMDAR}) can be adequately described by the simple current-voltage relation defined by Eqs. 2 and 3. However, because

I_{NMDAR} shows a strong nonlinearity with respect to voltage due to Mg^{2+} block of the NMDAR (see Fig. 3a, blue), I_{NMDAR} as a rule is modeled with the nonlinearity parameter $b(V_m)$ included:

$$I_{\text{NMDAR}} = G_{\text{NMDAR}} \cdot a(t) \cdot b(V_m) \cdot (V_m - E_{\text{NMDAR}}) \quad (9)$$

Like E_{AMPA} , E_{NMDAR} is usually 0 mV, and the value of G_{NMDAR} can vary widely. Again, expressions used to describe $a(t)$ include those defined in Eqs. 4, 5, 6, and 7.

The most commonly used expression for $b(V_m)$, which simulates the Mg^{2+} block of the NMDAR, is a simple Boltzmann function (Dubois et al. 2009) of the following form (Fig. 3b):

$$b(V_m) = 1/[1 + \exp(-(V_m - V_{0.5})/k)] \quad (10)$$

where $V_{0.5}$ sets the potential at which half of the NMDAR channels are blocked and k sets the steepness of the voltage dependence. Because $b(V_m)$ moves from values near 0 at hyperpolarized potentials to values near 1 at depolarized potentials, $b(V_m)$ describes the fraction of NMDARs that are *unblocked* rather than blocked. Another common expression of $b(V_m)$ is what is known as the Woodhull formalism (Woodhull 1973) which uses a kinetic model to describe the blocking action of an ion species from either inside or outside an ion channel (a 2-state model) or from both sides of the ion channel (a 3-state model). A 2-state model of Mg^{2+} blocking from the external side of the NMDAR channel, for example, can be described by the following equation:

$$b(V_m) = \frac{k_{-1}}{(k_{-1} + k_1)} = 1/(1 + k_1/k_{-1}) \quad (11)$$

where the Mg^{2+} binding rate $k_1 = [\text{Mg}^{2+}]_o K_1 \exp(-\delta_o \phi V_m/2)$, the unbinding rate $k_{-1} = K_{-1} \exp(-\delta_o \phi V_m/2)$, $[\text{Mg}^{2+}]_o$ is the external Mg^{2+} concentration, δ_o is the fraction of V_m that Mg^{2+} experiences at the blocking site, $\phi = zF/RT$, and z , F , R , and T have their usual meaning.

Substituting and rearranging terms, Eq. 11 reduces to the following equation:

$$b(V_m) = 1/(1 + [\text{Mg}^{2+}]_o/K_D) \quad (12)$$

where $K_D = K_{D0} \cdot \exp(\delta_o \phi V_m)$ and $K_{D0} = K_{-1}/K_1$. Equation 12 has two free variables, K_{D0} and δ_o , and is mathematically equivalent to the Boltzmann function in Eq. 10. The advantage of using Eq. 12 over Eq. 10 is that parameters K_{D0} and δ_o have a more physiological meaning than $V_{0.5}$ and k : K_{D0} is the Mg^{2+} dissociation constant at 0 mV and δ_o predicts the location of the Mg^{2+} binding site from the extracellular face of the NMDAR channel. A more complicated 3-state model can also be used to describe Mg^{2+} block of the NMDAR. For example, a 3-state model that includes Mg^{2+} permeation through the NMDAR channel has been used to simulate the incomplete Mg^{2+} block of the NMDAR in cerebellar granule cells (Schwartz et al. 2012). This particular 3-state model is described by the following equation:

$$b(V_m) = (k_{-1} + k_2)/(k_{-1} + k_1 + k_2) \quad (13)$$

where k_1 and k_{-1} are defined above, the rate of Mg^{2+} permeation $k_2 = K_2 \exp(-\delta_i \phi V_m/2)$, and δ_i predicts the location of the Mg^{2+} binding site from the intracellular face of the NMDAR channel. In the original Woodhull formalism, it was assumed $\delta_i = 1 - \delta_o$ (Woodhull 1973). Besides the experimental evidence that indicates Mg^{2+} permeates through the NMDAR channel, there is experimental evidence of two Mg^{2+} binding sites within the NMDAR channel, one that binds external Mg^{2+} and one that binds internal Mg^{2+} (Johnson and Ascher 1990). Hence, a 3-state model such as that described by Eq. 13, or the original 3-state Woodhull formalism that includes four rate constants, k_1 , k_{-1} , k_2 , and k_{-2} , may be necessary to adequately describe I_{NMDAR} .

Because Ca^{2+} is known to play an important role in intracellular signalling, including long-term modifications of synaptic strength, it is sometimes necessary to include Ca^{2+} dynamics in a synaptic model. For the I_{NMDAR} model described above, this is somewhat problematic

since it lumps together its underlying Ca^{2+} current with its other cationic currents, K^+ and Na^+ . This might also be true of the I_{AMPA} model since some AMPARs (those lacking a GluR2 subunit) pass Ca^{2+} ions. One of the simpler solutions to this problem is to simultaneously compute a Ca^{2+} current (I_{Ca}) that corresponds to I_{NMDAR} or I_{AMPA} , using the same parameters for $a(t)$ and $b(V_m)$. I_{Ca} for the NMDAR, for example, can be defined as follows:

$$I_{\text{Ca_NMDAR}} = G_{\text{Ca}} \cdot a(t) \cdot b(V_m) \cdot (V_m - E_{\text{Ca}}) \quad (14)$$

To use this equation, one needs to know the peak Ca^{2+} conductance (G_{Ca}) passing through the NMDARs. The value of the Ca^{2+} reversal potential (E_{Ca}) is often set to ~ 150 mV or might be described by the Goldman–Hodgkin–Katz equation (Hille 1992). Note that $I_{\text{Ca_NMDAR}}$ is not added to the electrical circuit defined by Eq. 1 since this current is already included in the circuit, via I_{NMDAR} . $I_{\text{Ca_NMDAR}}$ is only added to the part of the synaptic model that simulates $[\text{Ca}^{2+}]_i$ dynamics, which might also include contributions from voltage-dependent Ca^{2+} channels, Ca^{2+} buffers, Ca^{2+} stores, and Ca^{2+} pumps (DeSchutter and Smolen 1998; Sterratt et al. 2011).

Inhibitory GABA Receptor Currents

Most inhibitory synapses in the brain use either GABA (gamma-aminobutyric acid) or glycine as their neurotransmitter, and some use GABA and glycine together (Bowery and Smart 2006). Inhibitory synapses that use GABA make up a significant fraction of all synapses in the brain. At these synapses, GABA is released from the presynaptic membrane into the synaptic cleft. The released GABA then diffuses across the synaptic cleft and binds to postsynaptic transmembrane receptors which can be either metabotropic or ionotropic. The ionotropic receptors, also known as GABA_A receptors, are responsible for generating all or most of the IPSC and are therefore the basis of most

GABAergic synaptic models. For GABA_A receptors, binding of GABA triggers opening of their Cl^- -selective pore. The increased Cl^- conductance drives the local membrane potential toward the reversal potential of Cl^- , about -65 to -80 mV, thereby inhibiting the generation of action potentials.

The synaptic current generated by GABA_A receptors (I_{GABAR}) is classified as being either phasic or tonic. Phasic I_{GABAR} has a comparatively fast time course, with no residual component, and is mediated by receptors situated within or near the postsynaptic density (i.e., intrasynaptic receptors). Tonic I_{GABAR} , on the other hand, is a persistent current mediated by receptors outside the synapse (i.e., extrasynaptic receptors). Tonic I_{GABAR} is thought to be important for shunting inhibition and gain control of neuronal excitability (Farrant and Nusser 2005).

A typical model of phasic I_{GABAR} is as follows:

$$I_{\text{GABAR}} = G_{\text{GABAR}} \cdot a(t) \cdot (V_m - E_{\text{GABAR}}) \quad (15)$$

where G_{GABAR} is the peak GABAR conductance, E_{GABAR} is the Cl^- reversal potential, and $a(t)$ can be described by one of the Eqs. 4, 5, 6, and 7. Equation 15 can also be used to describe tonic I_{GABAR} by simply removing $a(t)$ from the expression.

Stochasticity

Up until now the description of synaptic models has been completely deterministic: on arrival of a presynaptic action potential, the model's postsynaptic response is identical in size and shape under basal conditions. However, it has long been known that real synapses show trial-to-trial variability due to the stochastic nature at every level of the synaptic signal cascade outlined in steps 1–6 above. For central synapses, the variability can be significant, in which case the addition of stochasticity to a synaptic model may be necessary.

A main source of synaptic variability arises from the stochastic nature of vesicle release. The

analysis of such variability at the neuromuscular junction led to the quantum hypothesis by Katz and colleagues (Katz 1969) which states that presynaptic action potentials are transmitted by the release of discrete packets of neurotransmitter, or quanta, into the synaptic cleft; moreover, the release of the quanta is not 100% reliable but probabilistic. For central synapses, a binomial model is often used to simulate stochastic quantal release, the simplest model being one that assumes a uniform quantal release probability (P) and uniform postsynaptic quantal response (Q) across a fixed number of quantal release sites (N_T). In this case, the success of quantal release (i.e., vesicular release) at a given release site is computed by drawing a random number u from the interval $[0, 1]$. If $u < P$, then quantal release is a success at that site and a postsynaptic response with amplitude Q is generated. Summing all successes across the N_T release sites results in the final postsynaptic response of the synapse. Figure 4a shows an example of such a simple binomial model, where $N_T = 4$, $P = 0.5$ and $Q = 0.25$ nS. Here, 20 repetitions resulted in a series of postsynaptic conductances (G_{syn} ; Eq. 3) with five discrete amplitudes (G_{max}) between 0 and 1 nS, due to the five possible combinations of Q , including 0 for the case of failures at all release sites. A more complicated binomial model of quantal release might assume a nonuniform Q at individual release sites (i.e., intrasite variability) and a nonuniform Q between release sites (i.e., intersite variability) (Silver 2003). Figure 4b shows an example of such a model, where both types of nonuniform Q were generated from two different Gaussian distributions. Here, 20 repetitions resulted in a series of postsynaptic conductances each with a unique amplitude between 0 and 1.1 nS. An even more complicated binomial model of quantal release might include variability in the vesicle release time course by adding a time delay between the arrival of the presynaptic action potential and the onset of the postsynaptic conductance response. Such a model is shown in Fig. 4c. Here, the delay in release sometimes reveals the quantal release events in isolation.

Modeling Synapses, Fig. 4 Binomial model of a synapse containing four independent release sites (N_T), each with a vesicle release probability of 0.5 (P) and peak postsynaptic receptor conductance of 0.25 nS (Q). (a) Overlaid G_{syn} of the binomial model for 20 repetitions in response to a presynaptic action potential (top red trace). **Inset** shows schematic of a presynaptic neuron with four release sites (left) making a synaptic contact with a postsynaptic neuron (right). (b) Same as (a) but now with added intrasite variability of Q (Gaussian distribution with a coefficient of variation $CV_{\text{QS}} = 0.25$) and intersite variability of Q (Gaussian distribution with $CV_{\text{QII}} = 0.30$). (c) Same as (b) but now with added variability in the release time at each release site. Dashed red line defines the release time course function used to generate the latencies

Synaptic Depression and Facilitation

Besides the variability of the synaptic strength under basal conditions discussed in the previous section (i.e., the variability in Q), there is also a use-dependent modulation of synaptic strength on short time scales (Eccles et al. 1941; Zucker and

Regehr 2002). During trains of closely spaced action potentials, for example, some synapses show a decrease, or depression, in the EPSC amplitude (typically at synapses with a high release probability), whereas other synapses show an increase, or facilitation, in the EPSC amplitude (typically at synapses with a low release probability), and some show signs of both during the same train (see, e.g., Dittman et al. 2000). In all likelihood, synapses probably exhibit both depression and facilitation together, but because one predominates both are not readily apparent.

Although the source of synaptic depression can vary, the main source is thought to be the finite time it takes to clear and replenish emptied release sites. A common model used to describe such a process is known as the depletion model, first described by Liley and North (1953). In a modern version of the Liley and North model (Fig. 5a), a fixed number of release sites (N_T) is supplied by a large pool of vesicles (assumed to be large enough so that it never empties) at a rate k_1 . Once a vesicle docks at a release site, it stays docked until the arrival of an action potential (although some models might simulate undocking at a slow rate defined by k_{-1}). If the number of release sites filled with a vesicle at any given time is defined by N , then the number of empty release sites equals $N_T - N$. At the arrival of an action potential, say at time t_s , a fraction (P) of N is released into the synaptic cleft, thereby triggering a postsynaptic response in proportion to $N \cdot P$. The change of N with respect to time after release is then described by the following differential equation:

$$dN/dt = k_1(N_T - N) \quad (16)$$

If one assumes all sites are filled under steady-state conditions, Eq. 16 has the following solution:

$$N = N_T + (N_{s+} - N_T) \cdot \exp(-(t - t_s)/\tau_r) \quad (17)$$

where $\tau_r = 1/k_1$ and N_{s+} is the value of N immediately after vesicle release at time t_s . However,

Modeling Synapses, Fig. 5 Modeling synaptic short-term depression and facilitation. (a) Cartoon of a vesicle depletion model containing a large pool of vesicles (blue circles) and a fixed number of vesicle release sites (N_T , black), N of which are filled with a readily releasable vesicle (the number of free release sites is therefore $N_T - N$). The arrival of an action potential triggers a fraction of the readily releasable vesicles to be released ($N \cdot P$), increasing the number of empty release sites. Empty release sites are refilled with a vesicle at a rate k_1 . The normalized resource variable $R = N/N_T$. (b) Example simulation of the depletion model in (a) using Eqs. 22, 23, 24, 25, and 26 ($\tau_r = 20$ ms, $P_\infty = 0.4$, $\Delta_p = 0.6$, $\tau_f = 20$ ms). The time evolutions of R , P , and $R \cdot P$ are shown at top and the resulting G_{syn} at bottom (green line) for a 100 Hz train of action potentials with random time intervals. Gray line shows G_{syn} in the absence of depression and facilitation

most depletion models express Eqs. 16 and 17 with respect to the fraction of release sites filled with a vesicle (i.e., N/N_T), also known as site occupancy. In this case, Eqs. 16 and 17 become

$$dR/dt = k_1(1 - R) \quad (18)$$

$$R = 1 + (R_{s+} - 1) \cdot \exp(-(t - t_s)/\tau_r) \quad (19)$$

At the arrival of an action potential, $R \cdot P$ is now released into the synaptic cleft. The value $R \cdot P$ is then used to scale the postsynaptic response (e.g., $G_{\max}$ in Eq. 3).

Unlike synaptic depression, synaptic facilitation is thought to arise from a single source, that source being the accumulation of intracellular Ca^{2+} near vesicle release sites (Katz and Miledi 1968; Zucker and Regehr 2002). This explanation of facilitation is known as the residual Ca^{2+} hypothesis. Since Ca^{2+} plays an integral part of synaptic transmission (Fig. 1a, step 2), facilitation is thought to be a universal characteristic of synapses. However, facilitation has not always been apparent at some synapse types, most likely due to the presence of strong depression or strong intracellular Ca^{2+} buffering. A typical model implementation of synaptic facilitation is similar to that of depletion and goes as follows: at the arrival of an action potential at t_s , the probability of release, P , is instantaneously increased by a scale factor Δ_p , after which P decays back to its steady-state value P_{∞} . The change of P with respect to time after the action potential is then described by the following differential equation:

$$dP/dt = (P_{\infty} - P)/\tau_f \quad (20)$$

which has the following solution:

$$P = P_{\infty} + (P_{s+} - P_{\infty}) \cdot \exp(-(t - t_s)/\tau_f) \quad (21)$$

where τ_f is the time constant for recovery from facilitation and P_{s+} is the value of P immediately after an action potential at time t_s . Note that this type of facilitation model does not explicitly model intracellular Ca^{2+} ; rather, Ca^{2+} entry and the effect of Ca^{2+} on P are combined into the same instantaneous event, i.e., the instantaneous increase in P . More complicated facilitation models will explicitly simulate intracellular Ca^{2+}

dynamics, possibly including Ca^{2+} buffering and extrusion, and equate P with $[\text{Ca}^{2+}]_i$.

An example of a simple simulation of a depletion model that includes both synaptic depression and facilitation is shown in Fig. 5b. Here, a random train of action potentials arrived at times t_s , where $s = 1, 2, 3, \dots$, and values for R and P at t_s were computed via the following equations (derived from Eqs. 19 and 21):

$$R_s = 1 + (R_{s-1} - 1) \cdot \exp(-(\Delta t_s)/\tau_r) \quad (22)$$

$$P_s = P_{\infty} + (P_{s-1} - P_{\infty}) \cdot \exp(-(\Delta t_s)/\tau_f) \quad (23)$$

where s denotes the current spike stimulus, $s - 1$ the previous spike stimulus, and Δt_s the interstimulus time ($\Delta t_s = t_s - t_{s-1}$). Values for R_s and P_s were then used to scale the postsynaptic conductance via the following equation:

$$G_{\max} = Q \cdot N_T \cdot R_s \cdot P_s \quad (24)$$

where Q is the quantal conductance (see $G_{\max}$ in Eq. 3). Finally, new values for R and P at t_s were computed via the following equations:

$$R_s = R_s(1 - P_s) \quad (25)$$

$$P_s = P_s + \Delta_p(1 - P_s) \quad (26)$$

These values for R_s and P_s then became R_{s-1} and P_{s-1} in Eqs. 22 and 23 on arrival of the next action potential, creating a recursive algorithm. Note that for the first action potential (i.e., $s = 1$), $R_{s-1} = 1$ and $P_{s-1} = P_{\infty}$.

The story of synaptic depression and facilitation can be more complicated than just described. Besides presynaptic depression due to the depletion of vesicles, some synapses exhibit depression due to desensitization of postsynaptic neurotransmitter receptors (Jones and Westbrook 1996). Other synapses show signs of use-dependent vesicle replenishment rates (i.e., τ_r). Longer lasting forms of depression and facilitation also occur, including long-term depression and potentiation. With a few adjustments, however, these additional

forms of depression and facilitation can be incorporated into the simple depletion model just described (Hennig 2013).

Electrical Synapses: Gap Junctions

As stated above, gap junctions create a direct electrical connection between the presynaptic and postsynaptic membrane via interlinking ion channels (connexins) spanning both membranes. Because of the direct connection, gap junctions are fast and pass signals bidirectionally. However, the signals tend to be highly low-pass filtered (Galarreta and Hestrin 1999). Most neurons connected via gap junctions are GABAergic, and those connected tend to be of the same neuronal type (McCracken and Roberts 2006). Gap junctions are important for generating neural synchronization (Bennett 1997).

The easiest way to simulate a gap junction in a Hodgkin–Huxley-type model is to place a resistor between the presynaptic and postsynaptic membrane. The current flowing into the postsynaptic membrane compartment is then described by the following equation:

$$I_{\text{gap}} = G_{\text{gap}}(V_{\text{m}} - V_{\text{pre}})$$

where G_{gap} is the gap junction conductance and V_{pre} is the presynaptic membrane potential. In most models, G_{gap} is a constant; however, G_{gap} can also be a function of V_{m} , as this conductance can show voltage dependence. In some instances a more complicated representation of a gap junction is implemented with a resistor in parallel with a capacitor.

MOOSE, the Multiscale Object-Oriented Simulation Environment

Niraj Dudani, Upinder S. Bhalla and Subhasis Ray
National Centre for Biological Sciences, Tata Institute of Fundamental Research, Bangalore, Karnataka, India

Definition

MOOSE (Multiscale Object-Oriented Simulation Environment) is a general-purpose biological simulator with an emphasis on systems biology and computational neuroscience.

Detailed Description

Introduction

Mathematical modeling and computer simulations constitute an increasingly important approach for understanding complex biological systems. MOOSE is a modern, free, and open-source software designed for the modeling and simulation of a wide range of detailed biological phenomena spanning many spatial and temporal scales. MOOSE uses standard C++ with a variety of open-source libraries and currently runs on laptops, workstations, and large parallel machines that support Linux.

This section explains the basic features of MOOSE by examining the terms in its acronym: Multiscale Object-Oriented Simulation Environment.

MOOSE is a **multiscale** simulator. This means that it can simulate processes at many levels of detail and at many timescales. This

includes the movement and interactions of individual molecules, large reaction pathways, entire cells, and even large networks of neurons. The typical timescales range from microseconds for some neuronal phenomena to hours or even days for some biochemical reactions.

Not only can MOOSE handle each of the above phenomena separately, it also supports “true” multiscale calculations where processes belonging to many spatial and temporal scales are coupled together in a single, large simulation. For example, it has been used for models involving detailed and mutually interacting models of electrical and chemical signaling events in neurons.

MOOSE is **object-oriented**. Fundamental biological entities like molecules, reactions, synapses, and dendritic segments are represented as “objects.” Objects have “fields” which represent properties. For example, a `Molecule` object may have a field which holds its concentration value. The user can monitor state variables by inspecting these fields and specify model parameters by modifying these fields.

Objects serve as building blocks of models, and the user can compose a model by connecting objects together. Each of the connections is called a “message.” Messages serve not only as a way to represent relationships in a model but also as conduits through which information can flow during a simulation. In this way, objects and messages allow for flexible model building and present an intuitive interface for user interaction.

Finally, MOOSE is not just a simulator, but is also a **simulation environment**. Existing simulators (Bower and Beeman 1998; Carnevale and Hines 2006; Bergmann et al. 2011) excel within limited domains of computational biology. While they implement fast algorithms for handling certain biological processes, these implementations tend to be tightly coupled with the rest of the simulator. This tight coupling makes it very difficult to extend the capability of such a simulator. In MOOSE, new algorithm implementation is facilitated by an infrastructure that supports seamless and transparent mapping between specialized numerical engines and the object-oriented

specification of the model. MOOSE thus separates the process of algorithm development from the much larger infrastructure that a full-fledged simulator requires.

In MOOSE, one can introduce new biological concepts simply by adding new object types. Newer object types can talk to existing ones using the clean and well-defined interface of fields and messages. New objects automatically plug into the infrastructure provided by MOOSE, such as scripting and model description languages, file I/O, and parallelization.

MOOSE is a free and an open-source software and is licensed under the Lesser GNU Public License, version 2. The basic infrastructure and numerics are written in C++ for speed, and Python bindings allow for scripting and access to a host of Python-based libraries and simulators. MOOSE also has a graphical user interface, with model inspection, plotting, and 3D graphics for spatial models. All these communicate with MOOSE through the Python interface, thus insulating interface development from the underlying C++ core. MOOSE can run on a range of hardware: from laptops to supercomputing clusters. The MOOSE project is based at <http://moose.ncbs.res.in/>.

Architecture

Numerics

As mentioned above, MOOSE objects are used to represent biological concepts. In addition to this, most objects can perform calculations to advance their state variables. The exponential Euler numerical scheme is used for these calculations, because it is object local and is simple to implement.

For almost all domains, specialized, higher-order numerical methods exist which are faster, more robust, and more accurate. They are faster because they contain domain-specific optimizations and, being higher-order methods, can afford much longer time steps for the same accuracy. In addition to being algorithmically faster, they are faster also because they make much more efficient use of computer resources. While these advanced numerical schemes are great for speed and

accuracy, they do not offer the intuitive interface that objects and messages do. MOOSE achieves the best of both worlds by retaining objects and messages for the user to interact with, but transferring their computational responsibilities to solvers. A single solver typically takes over calculations of a large number of objects, and any requests or messages meant for an object are transparently rerouted to the corresponding solver. This avoids the overhead of message-passing and allows excellent use of fast cache memory.

MOOSE makes it easy to incorporate new numerical methods via these solvers. A host of specialized numerical engines have already been implemented. A neuronal solver has been implemented based on the Hines algorithm (Mascagni and Sherman 1998), which is a fast numerical scheme for simulating the electrical activity in branched neurons and their networks. Similarly, reaction-diffusion computations of large biochemical pathways can utilize a range of numerical algorithms supported by the GNU scientific library. The default engine for reaction systems uses an adaptive time-step Runge-Kutta-Fehlberg (RKF45) method provided by the GNU scientific library, and a custom backward Euler implicit method is being prototyped for diffusion in branched neurons. For chemical reactions in sufficiently small volumes, stochastic effects become important and are handled by an implementation of the Gillespie algorithm. For even smaller volumes, it is important to simulate each individual molecule separately. For this, the SMOLDYN Monte Carlo simulator (Andrews et al. 2010) has been adapted to run as an engine inside MOOSE. Finally, a steady-state solver allows for the prediction of a steady state of biochemical reactions using analytical methods.

Scheduling

MOOSE has a sophisticated scheduling system that cleanly handles the varied timescales that exist in a multiscale simulation. Different parts of a simulation can be running at completely different and arbitrary time steps, and all the calculations will take place at the right time and in the right order.

Parallelism

MOOSE can run in parallel on large supercomputing clusters. It supports completely transparent parallelism. This means that the user can write a simulation script in the normal, serial, fashion, and MOOSE will handle the partitioning, communication, and load balancing. The user, and to a large extent even the MOOSE developer, can interact with objects directly without needing to know where on a cluster they reside.

Interfaces and Interoperability

Python Interface

MOOSE offers Python bindings which allow full access to all MOOSE capabilities. Python is a well-supported high-level language with an emphasis on clarity, maintainability, and rapid development. The user also has access to a large trove of in-built Python utilities and third-party tools for analysis, plotting, graphics, etc. This allows the user to carry out simulation and post-processing in a single script, using their favorite Python libraries. For these reasons Python has steadily gained popularity in scientific computing over the last decade. Since many other simulators also have Python bindings, this opens up the possibility of multiple simulators being used synergistically in a single, large, simulation (Ray and Bhalla 2008).

Graphical Interface

MOOSE has a fully-featured graphical user interface (GUI) built using the Qt framework, as supported by Python. Using the GUI, the user can load models, run simulations, and view results as plots and graphical representations. OpenGL-based 3D graphics allow one to visualize spatial models (e.g., networks of branched neurons) and their state during a simulation. Models can also be inspected and edited using generic widgets in the GUI. In addition, domain-specific graphical toolkits allow for more advanced model interaction. For example, Kinetikit is a powerful toolkit for editing, inspecting, and visualizing the structure and runtime state of chemical kinetic models. Similarly, Neurokit, a toolkit allowing similar interactions with neuronal models, is under development.

In addition to the above general tools, a host of graphical educational tutorials have also been included. Each tutorial is a self-contained graphical program illustrating important concepts in computational neuroscience, like Hodgkin-Huxley channels, Izhikevich spiking neurons, etc. All graphical libraries used in making the GUI (Qt, OpenGL, matplotlib) are multi-platform libraries, allowing the GUI to run on all the major operating systems.

Interoperability and Standards

A major problem in the field of computational biology has been that each simulator has its own custom file formats for representing models and simulations. Any researcher wishing to run the same simulation in a different simulator would have to deal not only with porting models from one language to another but also with a host of simulator-specific idiosyncrasies. This always turns out to be a highly arduous and error-prone process. To overcome these problems, the community has standardized XML-based model description languages which are being adopted by many simulators. MOOSE already supports the major modeling languages: SBML (Systems Biology Markup Language) and NeuroML (Hucka et al. 2010; Gleeson et al. 2010). SBML is a mature specification which covers a large number of aspects of modeling of biochemical pathways. NeuroML is a language used to describe highly detailed models of neurons and their networks. In addition, MOOSE aims to support the Network Interchange format for NEuroscience (NineML) as the specification matures. Finally, MOOSE is one of the first simulators with multi-scale capability, and it provides a key test bed for implementations of multiscale model definition standards.

Developers and Support

MOOSE has been under development for over 5 years, and the principal architect is Dr. U.-S. Bhalla. The core development team includes Subhasis Ray, Niraj Dudani, Harsha Rani, and Aditya Gilra. Several other developers have participated, and there has been valuable community

feedback for the MOOSE project. The MOOSE project receives continuing core support from the National Centre for Biological Sciences. It has also been supported by several grants including NIH/NIGMS SBCNY (SBCNY6637) and the Department of Biotechnology, India.

Morphoelectrotonic Transform

William R. Holmes
Department of Biological Sciences, Ohio
University, Athens, OH, USA

Definition

A morphoelectrotonic transform is a graphical mapping from morphological into electrotonic

space where the physical length of each dendritic section is replaced by a distance measure, keeping diameter and morphological orientation constant, to provide a direct, intuitive, and functional measure of intracellular signaling.

Detailed Description

From cable theory, the steady-state decay of voltage with distance along a semi-infinite cable is given by $V(x) = V_0 \exp(-x/\lambda)$ where x is physical distance and λ is the space constant. While this solution is useful for describing passive voltage decay in axons, it is not appropriate for estimating voltage decay in dendrites whose electrotonic lengths ($L = \ell/\lambda$) are not infinite and in fact are often less than 1.0. As shown by Rall and Rinzel (1973), voltage attenuation in dendritic trees depends strongly on boundary conditions and is asymmetric in that attenuation *out* from the soma is typically very different from attenuation *in* to the soma. Electrotonic transforms and morphoelectrotonic transforms have been developed to express voltage attenuation in dendritic trees in an intuitive and quantitative manner to gain an understanding of the dependence of intracellular signaling on morphology.

In morphoelectrotonic transforms, the physical length of each neurite is replaced by a distance measure while keeping diameter and morphological orientation constant. Several distance measures are possible. For example, physical distance can be transformed to electrotonic distance $X = x/\lambda$. However, this transform does not provide a direct measure of voltage attenuation except for the case of an infinite cylinder. A transform that has been found to be useful for dendritic trees is the log attenuation L_{ij} defined as the natural log of the voltage attenuation spreading from point i to point j or $\log(A_{ij}) = \log(V_i/V_j)$. Here the length of each dendritic section is replaced by the log attenuation between the ends of the section, i and j , in the direction of interest. This transform has a number of useful properties (Tsai et al. 1994; Zador et al. 1995) including asymmetry ($L_{ij} \neq L_{ji}$) and additivity ($L_{ik} = L_{ij} + L_{jk}$ for j on the path between i and k). The asymmetry property reflects the fact that voltage

attenuation from dendritic tip *in* toward the soma is much greater than voltage attenuation from the soma *out* to dendritic tips. The additive property allows this transform to provide a direct, straightforward logarithmic relationship to describe attenuation between any two points in a dendritic tree, e.g., $L_{ij} = 1$ means that there is an e-fold drop in voltage from point i to point j .

Given the asymmetry, morphoelectrotonic transforms are computed separately for voltage attenuation *in* toward the soma and *out* from the soma to dendrites and also separately for DC and AC inputs. The simulator NEURON provides several impedance tools, one of which can be used to display the log-attenuation morphoelectrotonic transforms of a neuron for a given input frequency and given points of reference in the neuron.

Another morphoelectrotonic transform, entirely analogous to the log-attenuation transform, depicts the cell morphology in terms of propagation delay of synaptic signals through the dendritic tree (Agmon-Snir and Segev 1993). The delay is defined as the difference in centroids or the average or center of gravity of the signal. Both the log-attenuation transform and the propagation delay transform have been computed for a number of different cell types, and some dramatic differences have been noted (Zador et al. 1995; Tsai et al. 1994), suggesting morphology plays different roles in signaling in different cells.

Morphologically Detailed Cellular and Pool Motoneuron Models

Sherif M. Elbasiouny^{1,2} and Mohamed H. Mousa²

¹Department of Neuroscience, Cell Biology, and Physiology, Wright State University, Dayton, OH, USA

²Department of Biomedical, Industrial and Human Factors Engineering, Wright State University, Dayton, OH, USA

Definition

Morphologically detailed motoneuron models refer to a class of motoneuron (MN) models that are developed using experimentally derived, three-dimensional digital reconstructions of MN morphology (Fig. 1, left panel). In contrast to models with reduced morphological detail (Fig. 1, right panel), these models offer more accurate spatial resolution and allow realistic distribution of electrical properties.

Detailed Description

In a computer simulation, each part of the membrane is represented by an isopotential (i.e., fixed potential) compartment governed by a system of differential equations (see ► [“Compartmental Models of Spinal Motoneurons”](#)). These equations calculate the membrane electrical properties and ion channel behaviors/kinetics. Therefore, in order to have accurate spatial resolution, each compartment should be very small in length ($<0.1\lambda$, λ is the space constant) (Fleshman et al. 1988; Clements and Redman 1989). Because of the intricacy of a MN's structure, a morphologically detailed computer model would typically have thousands of compartments to fully represent the MN. Simplified computer models (also known as “equivalent cable models” or “reduced models”), on the other hand, represent the dendritic morphology with a single unbranched cable which contains membrane surface area equivalent to all real dendrites combined – thus “equivalent cable.” This cable usually comprises 10–50 compartments (but might sometimes only contain one).

M

Development of Computer Models with Realistic Morphology

The first step in constructing a morphologically detailed computer model is importing the three-dimensional morphology of the cell, which is

Morphologically Detailed Cellular and Pool Motoneuron Models, Fig. 1 A morphologically detailed model (left) versus its reduced counterpart for the same MN [cell 43c5, originally published in Cullheim et al. 1987]

usually obtained from the reconstruction of intracellularly stained or retrograde-labeled MNs. Examples of reconstructed morphologies are available through the online database NeuroMorpho. Org (<http://neuromorpho.org/neuroMorpho/index.jsp>). The second step in model development is matching the passive electrical properties of the model cell to experimental data. This step involves setting the passive membrane parameters [e.g., specific transmembrane resistance (R_m), specific axial membrane resistance (R_a), and specific membrane capacitance (C_m)] of each compartment of the model cell to replicate those electrical properties in which active conductances have little or no contribution (e.g., MN input resistance, time constants, electrotonic length). The third step is matching the active electrical properties of the model cell to experimental data. This is the point at which decisions are made on what active conductances need to be included and what their spatial distributions on various cell structures should be (soma, initial segment, and dendrites). The ionic current, I_{ion} , mediated through each active conductance can be described by the following general expression:

$$I_{ion} = g_{ion} \times (V_m - E_{ion}) \quad (1)$$

$$g_{ion} = \bar{g}_{ion} \times m^n \times h^l \quad (2)$$

in which g_{ion} is the varying conductance of the ion channel; $\bar{g}_{ion}$ is the maximum conductance of the ion channel; m and h are the activation and inactivation state variables, respectively; and n and l are the order of activation and inactivation, respectively.

For each membrane state variable (η), the time and voltage dependence are given by

$$d\eta/dt = \alpha_\eta(1 - \eta) - \beta_\eta\eta \quad (3)$$

$$\tau_\eta = 1/(\alpha_\eta + \beta_\eta) \quad (4)$$

The spatial distribution, densities ($\bar{g}_{ion}$), and activation and inactivation kinetics (α_η , β_η , τ_η) of individual active conductances are then adjusted to produce comparable firing behaviors to

experimental data (see ► [“Compartmental Models of Spinal Motoneurons,”](#) for examples on how calcium channels are distributed in order to replicate plateau potentials successfully). A computer model would be validated if it matches multiple sets of experimental data (passive and active) under various experimental conditions (current clamp and voltage clamp). To test the robustness and validity of model results, sensitivity analysis is usually required on critical model parameters. In this process, model parameters that greatly impact the simulation results are first identified. Then, their values are varied within the range observed in experimental recordings in order to assess the dependence of output model behaviors on the variation in those parameters.

Utility of Morphologically Detailed MN Models

Simplified MN models were developed as a necessary means to make simulations computationally efficient, an issue which is being resolved by increasing computational power. Morphologically detailed computer models are now more feasible and offer numerous attractive features. First, they can be used to investigate both the passive and active properties of MNs. In contrast, the dendritic reduction of reduced models is unable to accurately reproduce active conditions (Rall 1962; Holmes et al. 1992). Second, the incorporation of full MN morphology allows these detailed models to simulate MN firing behaviors more accurately, whereas reduced models are unable to simulate some MN firing behaviors (Jackson and Cauler 1997; Hendrickson et al. 2011). This is because the equivalent membrane surface area, even when optimized to match a real MN's electrical properties, is not the only factor which affects active conductances: The morphology of dendrites – the number of branches and the direction of branching – also affects dendritic active conductances. Third, morphologically detailed models contain enough anatomical data to produce unique solutions to questions about passive properties –

that is, a single scenario or a single set of model parameters can account for all aspects of empirical data (Holmes and Rall 1992; Holmes et al. 1992). This is in contrast to reduced models, which suffer great *redundancy* of model parameters – that is, they produce too many potential solutions to a question or too many candidate mechanisms to feasibly test in experiments (Holmes and Rall 1992; Holmes et al. 1992). Fourth, morphologically detailed models allow investigation of scientific questions impacted by the specific spatial distribution of various cellular properties (e.g., spatial distribution of dendritic ion channels and synaptic inputs), which are not faithfully represented in reduced models (Elbasiouny et al. 2005). Finally, in neurological conditions, such as spinal cord injury or amyotrophic lateral sclerosis, the MN experiences massive pathological changes in dendritic morphology (Kitzman 2005; Amendola and Durand 2008). Because accurate modeling of changes in dendritic structure is critical for accurate simulation of these

pathologies, morphologically detailed models would be more appropriate to use in such neurological conditions, as opposed to reduced models which lack dendritic morphological detail.

Simulations of Pool Models Formed from Morphologically Detailed MN Models

Although morphologically detailed cell models are useful for studying MN behaviors at the cellular level, muscle and network behaviors require highly detailed pool models in which a number of MNs are included to represent the pool of spinal neurons innervating the muscle of interest (Jiang et al. 2015; Allen and Elbasiouny 2018). These pool models (Fig. 2) could then be used to examine the neuronal drive to the muscle, the recruitment pattern of MNs, and the total as well as individual forces and EMG signals generated by the different fiber types comprising the muscle. For example,

M

Morphologically Detailed Cellular and Pool Motoneuron Models, Fig. 2 Example of a MN pool model, from right to left: a morphologically detailed MN model is activated by triangular synaptic commands. Somatic action potentials are generated; these can then be used to calculate

the force and EMG signals of each motor unit and the compound action potential, total force, and EMG from the whole pool. (Adapted from Allen and Elbasiouny (2018) with permission)

Morphologically Detailed Cellular and Pool Motoneuron Models, Fig. 3 Rheobase versus input resistance for pool models of different design features. (a) Pool model with overlap in MN-type cellular properties. (b) Pool model with discrete ranges of MN-type properties (i.e., no overlap). (c) Homogenous pool model in which MN

types are modeled using generic cell templates with varied electrical properties. (d) Pool model which simulates heterogeneity in individual MN properties within MN types. (e, f) The recruitment range of MN types in each pool model. (Adapted from Allen and Elbasiouny (2018) with permission)

Fig. 2 shows an example of a motor pool from Allen and Elbasiouny (2018): 51 morphologically detailed cells were incorporated into a pool model in order to simulate the motor nerve's neural activity, as well as the resulting compound action potentials, muscle EMG, and force from individual MN spikes. With such a pool, muscle and individual motor unit behaviors could be examined under different conditions and in response to different synaptic inputs.

Despite the advantages of 3D morphologically detailed pool models, there are challenges in their operation and development. Operation of a pool model formed of morphologically detailed cells requires high computational power and involves long run times. Computational resources such as parallel supercomputer hardware [e.g., the Neuroscience Gateway (Sivagnanam et al. 2013)] are therefore critical for such simulations. In these simulations, the run time is determined by the complexity of individual model cells, the architecture of the pool model, and how cells communicate with each other. Accordingly, the run time will be governed by the slowest and most complex cell in the pool model.

Challenges in the development of pool models include consideration of several key design choices. Importantly, several design considerations were shown to have a strong impact on simulation predictions made by morphologically detailed MN pool models (Allen and Elbasiouny 2018). The features tested included (1) the number of model cells to include in the pool; (2) whether MN types were explicitly represented (slow-twitch vs. fatigue-resistant vs. fast-twitch); (3) whether MN types were modeled using generic templates versus those developed with distinct electrical and morphological properties; (4) whether different MN types were modeled with overlapping cellular properties or with discrete property ranges; (5) whether biological heterogeneity in cellular properties within MN types was simulated; and (6) whether comprehensive experimental data were available for model verification. Specifically, MN recruitment pattern, firing rates, and force data were shown to be affected by these design choices. Figure 3 illustrates four examples of possible design choices for the pool

model. Figure 3a shows a pool model with overlap in the properties of the different MN types. Figure 3b shows a pool model with discrete ranges (i.e., no overlap) in the properties of MN types. In Fig. 3a, b, MN types were modeled using discrete templates. Figure 3c, on the other hand, shows a pool model in which MN types were represented by generic templates and without overlap in properties. Finally, Fig. 3d shows a pool model which simulates biological heterogeneity in individual MNs within each type. As shown in panels e–h, the recruitment pattern of MNs was affected significantly by these design choices. In various scenarios, mixed or reverse recruitment patterns could be suppressed or exaggerated. In sum, incorporating high levels of detail into pool simulations requires careful consideration of the scientific question being investigated and of the cost vs. benefit of each feature, in order to choose the most relevant pool model design features. However, the effort is justified by the high fidelity of these simulations to the observed experimental data.

Morris–Lecar Model

Alla Borisyyuk

Department of Mathematics, University of Utah,
Salt Lake City, UT, USA

Definition

The Morris–Lecar model usually refers to a reduced two-variable model of action potential

generation, originally formulated by Morris and Lecar (1981) in their study of barnacle muscle electrical activity (for historical perspective see Lecar 2007). It was later popularized as a reduced model for neuronal excitability (Rinzel and Ermentrout 1998). The Morris–Lecar model is formulated in the Hodgkin–Huxley framework, with biophysically meaningful parameters and structure. It incorporates a slower hyperpolarizing potassium current and a fast non-inactivating calcium current (depolarizing and regenerative, like the Hodgkin–Huxley sodium current). In the simplest two-dimensional formulation, the activation of Ca^{2+} is assumed to be so fast that it is modeled as instantaneous. The model equations are

$$C \frac{dV}{dt} = -I_{ion}(V, w) + I_{app},$$

$$\frac{dw}{dt} = \phi [w_{\infty}(V) - w] / \tau_w(V),$$

where $I_{ion} = \bar{g}_{Ca} m_{\infty}(V)(V - \bar{V}_{Ca}) + \bar{g}_K w(V - \bar{V}_K) + \bar{g}_L(V - \bar{V}_L)$. The activation variable w is the fraction of open potassium channels and provides the slow voltage-dependent negative feedback as required for excitability, $\bar{g}_{Ca}$ and $\bar{g}_K$ are the maximal conductances of Ca^{2+} and K^+ , and $\bar{V}_{Ca}$ and $\bar{V}_K$ are the corresponding reversal potentials. Activation functions m_{∞} and w_{∞} are given by

$$m_{\infty}(V) = .5(1 + \tanh((V - V_1)/V_2)),$$

$$w_{\infty}(V) = .5(1 + \tanh((V - V_3)/V_4)).$$

and are shown in Fig. 1 together with voltage-dependent activation “time constant”

$$\tau_w(V) = 1 / \cosh((V - V_3)/(2V_4))$$

for a choice of parameter values, as summarized in the figure caption. The temperature factor ϕ speeds up the activation rate for increasing temperature:

$$\phi = 3^{(Temp-6.3)/10}.$$

As a two-dimensional dynamical system, the Morris–Lecar model, on one hand, readily lends

Morris–Lecar Model, Fig. 1 Time constants and the steady-state functions for the Morris–Lecar model. **(a1)** $m_{\infty}(V) = 0.5(1 + \tanh((V - V_1)/V_2))$ (dotted), $w_{\infty}(V) = 0.5(1 + \tanh((V - V_3)/V_4))$ (solid); **(a2)** $\tau_w(V) = 1/\cosh((V - V_3)/(2V_4))$, where $V_1 = -1.2$, $V_2 = 18$, $V_3 = 2$, $V_4 =$

30 , $\phi = 0.04$. Other parameters: $C = 20 \mu\text{F}/\text{cm}^2$, $\dot{g}_{Ca} = 4$, $V_{Ca} = 120$, $\dot{g}_K = 8$, $V_K = -84$, $\dot{g}_L = 2$, $V_L = -60$. (Reproduced with permission from Borisyyuk and Rinzel 2005)

itself to the use of the full strength of geometrical phase plane and bifurcation analysis. At the same time, it exhibits a diverse repertoire of interesting dynamical regimes and its parameters have direct biophysical interpretation.

The Morris–Lecar model has been used in many single-cell and network studies requiring a model, which is reduced (e.g., as a 2D projection of a higher dimensional model), amenable to analysis, yet biophysically interpretable. Many of the results from these studies are summarized and detailed in textbooks, e.g., Borisyyuk and Rinzel (2005), Ermentrout and Terman (2010), Izhikevich (2007), and Rinzel and Ermentrout (1998).

w -nullcline is simply the activation curve $w = w_{\infty}(V)$. Above this curve w decreases and below w increases (Fig. 2a).

The steady-state solution $(\bar{V}, \dots, \bar{w})$ of the system is the point where the nullclines intersect. It must satisfy $I_{ss}(\bar{V}) = I_{app}$, where $I_{ss}(V)$ is the steady-state $I - V$ relation of the model given by

$$I_{ss}(V) = I_{ion}(V, w_{\infty}(V)).$$

If I_{ss} is N-shaped, then there can be three steady states for some range of I_{app} . However, if I_{ss} is monotone (as is the case for the parameters in Fig. 1), then there is a unique steady state, for any I_{app} .

Detailed Description

Phase Plane Basics

This two-variable system's behaviors can be fully revealed in the phase plane. We start by finding the nullclines – the two curves defined by setting dV/dt and dw/dt individually equal to zero. The V -nullcline is defined by

$$-I_{ion}(V, w) + I_{app} = 0$$

and has a cubic-like shape. Below the V -nullcline in the $V - w$ plane $dV/dt > 0$, i.e., V is increasing, while above the nullcline V is decreasing. The

Excitable Regime

A system is said to be excitable when it has one stable steady state and the action potential (large voltage excursion) is evoked by a large enough brief stimulation. Figure 2a, b shows the responses to brief I_{app} pulses of different amplitude. After a small (subthreshold) pulse, the solution returns directly back to rest. If the pulse is large enough, Ca^{2+} current gets sufficiently activated, leading to even more depolarization and more Ca^{2+} influx. The solution trajectory heads rightward toward the right

Morris–Lecar Model, Fig. 2 Excitability in Morris–Lecar model. **(a)** Phase plane for excitable case (same parameter values as in Fig. 1). *Dotted lines* show V - and w -nullclines, and *solid lines* show solution trajectories with initial conditions $w_0 = 0.014173$, $V_0 = -20, -12, -10$, and 0 mV. **(b)** V Time courses for the same solutions as in

(a). **(c)** The peak value of the action potential V_{peak} versus initial value V_0 . Different curves correspond to different values of ϕ : from *top to bottom* ϕ increases (marked with an *arrow*) from 0.02 to 0.1 in 0.02 increments. (Reproduced with permission from Borisyuk and Rinzel 2005)

branch of the V -nullcline (upstroke) and follows the right branch upward (corresponding to the opening of K^+ channels). When the solution passes the knee (i.e., enough K^+ accumulates), it heads leftward (downstroke). The number of K^+ channels open reaches a maximum during the downstroke, as the w -nullcline is crossed. Then the trajectory follows V -nullcline's left branch (minimum of V) downward (K^+ channels close) and returns to rest.

Notice that if w is much slower than V (e.g., because ϕ is very small), the solution trajectories in the phase plane will be nearly horizontal during the upstroke and downstroke phases of the action potential. At these low temperatures, the trajectory of the action potential looks like a relaxation oscillation with very fast upstroke and downstroke, pronounced “plateau” near the maximum of the action potential and middle branch of the

V -nullcline serving as a threshold. However, at higher temperatures (larger ϕ), the flow in the phase plane is less horizontal and the shape and the maximum value of the spike are sensitive to the pulse size. If we plot the maximum voltage value during an action potential versus the size of the pulse that elicited that spike or initial condition V_0 , we get a continuous curve (Fig. 2c). The steepness of this curve depends on ϕ . This observation suggested that action potentials that look like stereotypical all-or-none events may have variable amplitudes at higher temperatures, which was later confirmed experimentally (Cole et al. 1970).

An action potential in the Morris–Lecar model can also be produced upon release from a prolonged hyperpolarizing stimulus. This phenomenon is termed post-inhibitory rebound. It occurs because K^+ channels that are normally open at rest

are closed by hyperpolarization, and thus the negative feedback near resting values of voltage is removed (see ► “[Postinhibitory Rebound and Facilitation](#)”).

Onset of Repetitive Firing

In the excitable regime resting steady state is stable. As applied current I_{app} is varied, the transition to periodic firing can happen when that steady state is destabilized. Stability of the steady state in the Morris–Lecar model is determined by the eigenvalues λ_1 and λ_2 of the Jacobian matrix J , evaluated at the steady state:

$$J = \left(\begin{array}{cc} -\frac{1}{C} \frac{\partial I_{inst}}{\partial V} & -\frac{1}{C} \frac{\partial I_{inst}}{\partial w} \\ \phi \frac{w'_{\infty}}{\tau_w} & -\phi \frac{1}{\tau_w} \end{array} \right) \bigg|_{(\bar{V}, \bar{w})}$$

The steady state is stable if and only if the real parts of both eigenvalues of the Jacobian matrix are negative. There are two main scenarios for the onset of oscillations.

First scenario (Andronov–Hopf bifurcation): a pair of complex conjugate eigenvalues crosses the imaginary axis moving from left to right. As a result the steady state becomes unstable and stable oscillations (a stable limit cycle) of small amplitude appear near the steady state. This is Andronov–Hopf bifurcation. At the bifurcation parameter value I_{bif} , we have $Re(\lambda_{1,2}) = 0$, and near bifurcation the amplitude of oscillations is proportional to $\sqrt{|I_{app} - I_{bif}|}$.

The scenario for the Andronov–Hopf bifurcation can also be viewed in terms of the trace of the Jacobian matrix: the negative trace corresponds to the stable steady state and at the bifurcation the trace becomes positive. For the Morris–Lecar model condition $tr(J) > 0$ means:

$$-\frac{1}{C} \frac{\partial I_{inst}}{\partial V} > \frac{\phi}{\tau_w} \quad (1)$$

Condition 1 can be interpreted as the rate of depolarization being faster than the negative

feedback’s rate (in particular, for negative feedback (represented by w) to be slow, the temperature cannot be too high). When this condition is met, periodic solution arises via Andronov–Hopf bifurcation, resulting in ongoing spiking activity. This periodic solution has a nonzero frequency associated with it, which is proportional to the $Im(\lambda_{1,2})$ – the imaginary part of the eigenvalues at the bifurcation parameter value – i.e., the repetitive firing emerges with nonzero frequency. Figure 3a shows snapshots of the nullcline positions and solution trajectories at different values of I_{app} (marked I_{excit} , I_{osc} , and I_{block} in Fig. 3b). Figure 3b, c shows the bifurcation diagram and the f – I relation, respectively. This is an example of the so-called Hodgkin type II spiking onset (see ► “[Excitability: Types I, II, and III](#)”).

The second scenario for onset of periodic spiking corresponds to the saddle–node on an invariant circle (SNIC) bifurcation. This can happen, for example, at increased values of $\dot{V}_K$ (corresponding physiologically to increased extracellular K^+ concentration). Parameters can then be chosen to result in three steady states: one on the left branch of cubic and the other two on the middle branch. If, additionally, ϕ is very small, then both middle and upper steady states can be unstable. Figure 4a1 shows nullclines and a schematic of stable and unstable manifolds of the middle fixed point, which is a saddle. As I_{app} is increased, the V –nullcline moves up and the saddle and the stable fixed point (node) coalesce and disappear (see Fig. 4a2, middle and right panels) leaving behind a periodic trajectory (a repetitive spiking solution). Exactly at the bifurcation value of parameter $I_{app} = I_1$, two coalescing points form a complex steady state, called saddle–node on an invariant circle (SNIC), and one eigenvalue becomes zero. For parameter values just above the bifurcation, the frequency of oscillations is proportional to $\sqrt{I_{app} - I_1}$, i.e., the periodic spiking emerges initially with zero frequency (or very large spiking period; see example in Fig. 4b). This bifurcation scenario is typical for Hodgkin type I excitability (see [Excitability: Types I, II, and III](#)). Figure 4c, d

thin-dashed curves, unstable steady state; thick solid curves, maximum and minimum V of the stable limit cycle; thick-dashed curves, maximum and minimum V of the unstable limit cycle. Parameter values are the same as in Fig. 1. (Reproduced with permission from Borisjuk and Rinzel 2005)

shows bifurcation diagram and $f-I$ curve for this case.

Bistability

There are many parameter combinations at which bistability is observed in the Morris–Lecar model. Bistability means that there are two stable structures (steady states or periodic orbits) coexisting at the same parameter values. Depending on initial condition, the solution will converge to one or the other attractor. A brief perturbation (of appropriate direction

and timing) can switch the solution between the attractors. For example, starting with the phase plane with three steady states, as in Fig. 4, different kinds of bistability can be observed by varying ϕ . At large values of ϕ , the middle steady state is unstable and the upper and lower ones are stable. The voltage can be switched from one constant level to the other by brief pulses. At intermediate values of ϕ , both middle and upper steady states can be unstable, but the upper steady state is surrounded by a stable periodic orbit. In this case there is bistability between the low-voltage resting state and depolarized repetitive firing. This example in

Morris–Lecar Model, Fig. 4 Type I excitability in Morris–Lecar model. Parameters are the same as in Fig. 1, except $V_3 = 12$ mV, $V_4 = 17$ mV, $\phi = 0.06666667$. (a) Schematics of phase plane. (a1) Schematic of phase plane for $I_{app} = 0 \mu A/cm^2$. The curves are slightly modified from the actual computed ones for easier viewing; in particular, actual trajectories would not have extrema away from nullclines. (a2) Schematic of change in phase plane with

change of I_{app} . (b) Time course of voltage for $I_{app} = 40 \mu A/cm^2$. (c) Bifurcation diagram. *Thin solid curves*, stable steady state; *thin-dashed curves*, unstable steady state; *thick solid curves*, maximum and minimum V of the stable limit cycle; *thick-dashed curves*, maximum and minimum V of the unstable limit cycle. (d) $f-I$ curve. *Dashed portion* corresponds to unstable periodic orbit. (Reproduced with permission from Borisjuk and Rinzel 2005)

which a stable rest state coexists with a depolarized limit cycle provides the basis for square wave bursting.

Another example of bistability, in a situation when only one steady state exists can be seen in Fig. 3b. There, close to Andronov–Hopf bifurcations, there is bistability between a stable steady state and a periodic orbit for narrow ranges of I_{app} .

Synonyms

Multi-objective evolutionary optimizations;
Multi-objective genetic algorithms

Definition

Multi-objective evolutionary algorithms (MOEAs) are any of the paradigms of evolutionary computing (e.g., genetic algorithms, evolutionary strategies, etc.) used to solve problems requiring optimization of two or more potentially conflicting objectives, without resorting to the reduction of the objectives to a single objective by the means of a weighted sum.

Detailed Description

The main ideas of evolutionary algorithms (EAs) are derived from the principles of variation and selection that are the foundation of Darwinian evolution (Beyer 2001). An evolutionary algorithm operates on a population of individuals, every one of which represents a candidate solution to a given optimization problem. Each individual is assigned a fitness value, which represents the “quality” of that potential solution. Solutions evolve by replication and become increasingly better, based on the mechanisms of natural selection and the two so-called genetic operators: crossover (recombination) and mutation.

Multi-objective evolutionary algorithms (MOEAs) form a special group of evolutionary algorithms that are specifically designed to deal with multiple, potentially conflicting objectives that need to be fulfilled in the process of

EA-driven optimization. Since rarely in multi-objective optimization (MOO) does there exist a single, optimal solution and, instead, one can usually expect a set of trade-off solutions, MOEAs, which by definition operate on entire populations of potential solutions, are well suited for MOO (Deb 2001).

The core concept in MOO is that of dominance relation. Formally, dominance is defined as follows (Deb 2001):

Let us assume that there are M objective functions, and the optimization goal is to minimize all of those objective functions (the same logic will apply to maximization and combined minimization/maximization, albeit with different signs). A solution x_1 is said to dominate the other solution x_2 , if both conditions 1 and 2 are true:

1. The solution x_1 is no larger (“worse”) than x_2 in all objectives, or $f_j(x_1) \leq f_j(x_2)$ for all $j = 1, 2, \dots, M$.
2. The solution x_1 is strictly smaller (“better”) than x_2 in at least one objective, or $f_j(x_1) < f_j(x_2)$ for at least one $j \in \{1, 2, \dots, M\}$.

The majority of MOEAs approach multi-objective optimization problems by targeting the so-called Pareto-optimal set of solutions. The set comprises all of the solutions from the entire population of solutions that do not dominate one another and are not dominated by any of the remaining solutions in the population. This means that within the set, one solution might be better than another solution in light of one of the objectives, but worse in some other objective, and vice versa. Therefore, there is no single “best” solution in the set. At the same time, for every solution outside of this set, one can always find a solution in this set which will dominate the former. Consequently, the Pareto-optimal set has the property of dominating all of the solutions that do not belong to this set, and thus all of its members can be considered better than the rest of the general population of solutions. The figure below illustrates a hypothetical example of a minimization problem in terms of two objectives. The solution represented by a red dot clearly dominates the three blue solutions, which are non-dominating

Multi-objective Evolutionary Algorithms,
Fig. 1 Illustration of the concepts of dominance and Pareto-optimality

with respect to each other. The green dots correspond to the Pareto-optimal front and as such dominate the rest of the population of solutions (Fig. 1).

Most contemporary multi-objective evolutionary algorithms apply various Pareto-based ranking schemes, which assign some kind of ranking to all the potential solutions in a given iteration, depending on to which Pareto-optima front (i.e., locally Pareto-optimal set) they belong. Examples of such evolutionary algorithms include the Non-dominated Sorting Genetic Algorithm-II (NSGA-II; Deb et al. 2002) and Strength Pareto Evolutionary Algorithm 2 (SPEA-2; Zitzler et al. 2001), which have become the standard approaches in multi-objective evolutionary optimization and are often utilized as benchmarks for other algorithms.

Applications

Multi-objective evolutionary algorithms have found applications in many areas of science, engineering, economics, business, and logistics. Since building neuronal models is basically a multi-objective optimization problem, where many goals are to be reached simultaneously (e.g., various aspects of the electrical activity must be matched, the cell morphology must be preserved,

the maximum complexity of the model must not be exceeded, etc.), MOEAs lend themselves perfectly to this application, as well. This is especially true in light of recent discoveries suggesting that the same functional neuronal activity can be produced by nerve cells of widely varying properties (e.g., Marder and Goaillard 2006), which has also been observed in modeling studies (e.g., Prinz et al. 2003). While most applications of multi-objective evolutionary algorithms in computational neuroscience pertain to parameter tuning of neuronal models (e.g., Druckmann et al. 2007; Smolinski and Prinz 2009), other applications such as classificatory decomposition of cortical evoked potentials (e.g., Smolinski et al. 2006) also exist.

Advantages and Disadvantages of MOEAs

One of the most significant advantages of multi-objective evolutionary algorithms is the straightforward generation of multiple trade-off solutions in a single run and the feasibility of utilization on large parameter search spaces, where most “brute-force” or manual approaches often fail. Another advantage – pertaining specifically to the problem of construction and/or tuning of neuronal models – is the ease of visualization of the parameter values in the form of scatterplots, which allows for a better comparison to biological data, as well as easier identification of relationships between parameters. This is possible due to the fact that the parameter search space explored by an MOEA is usually much more finely defined than competitive grid-based, “brute-force” approaches. In other words, while the range in the “brute-force” approach may reflect a three- to four-fold variation in the parameter values, and the granularity may allow for 5–10 possible values, incorporating up to 20-fold variation with hundreds of possible values for each parameter is not unheard of in an MOEA.

The biggest disadvantage of multi-objective evolutionary algorithms is the fact that the arrival at the global Pareto-optimal set is not guaranteed. Another disadvantage – as compared to

“brute-force” approaches to tuning of parameters of neuronal models – is the risk of missing large “chunks” of the parameter search space, if the space is not properly defined and/or premature convergence of the algorithm takes place. Finally, as the number of objectives being optimized increases, so does the computational complexity of the implementation.

Related Approaches

Several other nature-inspired computational intelligence approaches have been utilized in related applications. Those include particle swarm optimization (PSO) and simulated annealing (SA).

Definition

Multiscale brain connectivity refers to physical and functional connection patterns between a set of brain units on multiple levels of spatial extent. For large, complex systems such as the human brain, units may be defined as, e.g., single neurons (MRI, EEG/MEG), voxels, or brain areas on a microscopic, mesoscopic, or macroscopic scale, respectively. Connectivity between these units may be measured in terms of anatomical/structural connectivity (SC; Hagmann et al. 2010), the statistical relations between their functional states (functional connectivity, FC), or their inferred causal interactions (effective connectivity, EC; Friston 1994). Brain connectivity underlies signal propagation in neural networks and is thus crucial to understanding cognition and the brain’s information and activity flow in health and disease.

Detailed Description

Aspects of Brain Connectivity

In general, the term “connectivity” may refer to related but distinct concepts. In principle, all interactions in the brain are physical at the basic level, but they can be distinguished by their time scales and dynamics: SC represents the anatomical links between units, that is, by synapses or fiber bundles. FC is used to measure the bidirectional statistical interdependencies (correlations or synchronizations) of the functional states between units, independent of their structural connectedness (van den Heuvel and Hulshoff Pol 2010). Both SC and FC may change over time, but SC changes are typically much slower (from the order of minutes for synaptic plasticity) than for FC patterns. The latter are much more variable and span several time scales, because they depend on the dynamical evolution of the network units’ functional states and the temporal connectivity structure. Finally, EC refers to the “influence one neuronal system exerts over another” (Friston 1994). EC can be extracted from time series by statistical analysis of information flow (such as Granger causality, Ding et al. 2006), or dynamic causal modeling (Friston et al. 2003), and may further be constrained by knowledge about structural links. However, although these terms designate different concepts of brain connectivity, their distinction and precise definitions are not perfectly well defined and subject of discussion (Horwitz 2003; Fingelkurts et al. 2005).

In all cases, the connectivity is determined by all existing weighted or binary links between network units, and the number of links rises quickly with network size. In order to summarize, describe, and classify brain connectivity of complex networks, graph theory can be used and is an important tool in the study of brain connectivity (Bullmore and Sporns 2009). Graphs represent networks in an abstract form by vertices/nodes that are connected by edges and can be constructed for all types of connectivity. This way, it is possible to characterize brain networks in terms of various global and

local measures, such as network clustering coefficient, path length (the average number of nodes that have to be passed through to travel between two random nodes in the graph), or node centrality (the importance of a certain node in the graph). With graph theory, key brain regions can be identified, as well as network properties such as small worldness and subnetworks.

Connectivity at Multiple Scales

While it is possible and meaningful to describe the whole neuronal connectome in terms of synapses in simple organisms with only hundreds of neurons, more complex brains necessitate some levels of abstraction. In all brains, at the microscale, neurons form microcircuits through characteristic connection patterns, such as the characteristic connectivity patterns between neurons of different cortical layers. Here, single synapses and axons form the links between neurons. In larger brains, at the mesoscale, populations of similar neurons or microcircuits, e.g., in cortical columns, have been identified as functional units of encoding. These units may encode features or sets of features of our environment, such as locations in visual space in the visual cortex (Mountcastle et al. 1955). At this level, the units are defined functionally, and connectivity between units may be diffuse or patchy, depending on area and layer. Finally, brain areas based on Brodmann areas, cytoarchitectonic features and landmarks, and their white matter fiber tracts or functional relations are investigated to study large-scale brain networks and communications. Large-scale and multiscale networks and brain connectivity is a field of study that has been quickly growing since around the turn of the millennium and that has made major advances in beginning to reveal the principles of brain architecture (Craddock et al. 2013; Sporns 2010). At the same time, efforts are being made to map and model the whole human brain connectivity at multiple scales (Sporns et al. 2005; Markram 2006).

Connectivity in Large-Scale Network Models

In the study of the spontaneous activity of brain networks, large-scale brain network models are used to study the relationship between structural, functional, and effective connectivity. Typically, the models consist of nodes, connected by edges where indicated by empirically derived SC matrices from invasive tracing (CoCoMac) or (functional) diffusion (tensor/spectrum) magnetic resonance imaging (DTI/DSI). The interaction of the nodes depends on both the large-scale connectivity structure and the local node dynamics, which may be represented as single units, or by pools of smaller, interacting subunits, giving rise to multiscale dynamics in the models (Deco et al. 2011). Computational models have identified the importance of the underlying (spatiotemporal) structural connectivity matrix and its interaction with local dynamics in shaping FC patterns (Nakagawa et al. 2013), and in the future, they can potentially be used to study the effects of changes in dynamical properties and connectivity at multiple scales in different cognitive state or between healthy and diseased brains.

Multiscale Modeling of Purkinje Cells

Fidel Santamaria and Emmanuel A. Michaelides
UTSA Neurosciences Institute, The University of Texas at San Antonio, San Antonio, TX, USA

Definition

The Purkinje cell is one of the most extensively modeled neurons in computational neuroscience. Purkinje cells have large dendritic trees that contain more than 150,000 dendritic spines. While

dendritic spines are femto-liter cytosolic volumes with lengths of less than 2 μm , the dendritic tree can have a total length of hundreds of microns and thousands of femto-liters in volume. Thus, biochemical and electrical interactions take place over three orders of magnitude in space. Similarly, the time constant of activation of the different dendritic and somatic active conductances ranges from sub-milliseconds to almost 1 s (four orders of magnitude). Therefore, a comprehensive computational study of the Purkinje cell has to be done using multi-scale models and modeling techniques.

Detailed Description

Models of Purkinje cells range from perceptrons to detailed biochemical models of single synapses to biophysical models that take into account the intricate dendritic structure.

Passive Compartmental Models

The Purkinje cell is one of the first neurons to be modeled with a compartmental technique. These models consisted in digitizing the dendritic arbor and dividing it in finite elements where the passive properties (membrane resistance, membrane capacitance, and axial resistance) were fitted to replicate experimental measurements. These models were mainly used to study electrotonic decay and synaptic signal filtering.

Active Dendritic Models

The first compartmental model of a Purkinje cell with active conductances was developed by Pellionisz and Llinás (1977). A more detailed model was later developed by De Schutter and Bower (1994a, b). Ten different types of channels were added to the soma and dendrite. The model also included a calcium concentration calculation using a radial diffusion model within each compartment. The calcium concentration was used to activate calcium-activated potassium channels. The model was able to replicate the in vivo and

anesthetized in vivo firing rate statistics of Purkinje cells. This model has been modified and updated to study dendritic integration under multiple different experimental conditions.

Synaptic Plasticity Models

Long-term depression (LTD) of the parallel fiber to Purkinje cell synapse is a type of synaptic plasticity believed to be the cellular substrate of learning and memory in the cerebellum. Kuroda et al. (2001) developed a mass-action well-mixed model of a synapse undergoing LTD. This model has helped in determining that the biochemical network that underlies LTD is a type detector of intracellular calcium ion concentrations. The threshold to express LTD depends not only on the concentration of calcium ions but also on the temporal dynamics, which is better described as a leaky integrator of the calcium concentration signal. This mass-action model has been translated to a stochastic environment to study the reliability of LTD expression. The model has also been used to study short-term facilitation and depression.

Simplified Models

It has been proposed that the function of dendritic excitability is to compensate for the electrotonic decay of synaptic signals along the complex dendritic tree. In as such, the entire Purkinje cell can be collapsed into a single somatic compartment with a nonlinear integration function and a threshold. Furthermore, experimental and computation work suggests that the Purkinje cell can be treated as a perceptron, further simplifying the processing of synaptic input.

Definition

The strength of a synapse imparted by a presynaptic neuron onto its postsynaptic target can change as a function of the activity of the presynaptic neuron. This change is referred to as short-term synaptic plasticity. Networks of neurons connected with plastic synapses have the potential ability to display multiple stable solutions either at different parameter values or for the same set of parameters. This latter property is known as multistability. Self-consistency between the network frequency and the level of plasticity is needed to ensure multistability.

Detailed Description

The central nervous system (CNS) controls a vast array of behaviors that include both basic functions such as processing of sensory input (Sharp et al. 1990), regulating circadian rhythms (Piggins and Guldin 2011), coordinating motor output (Marder and Calabrese 1996), and more complex functions such as spatial navigation (O’Keefe 1991), decision making, and memory formation

(Treves and Rolls 1994). Although the CNS includes a large number of neurons and an even larger number of synaptic connections, these constitute a finite number of networks and few compared to the seemingly limitless number of behavioral tasks. This disparity strongly indicates that the networks of the CNS can reorganize to produce multiple outputs.

The output of a neuronal network can be quantified in a number of ways. The firing rate of the network neurons, for example, may encode information or, alternatively, the output may be coded in the pattern of activity of sub-networks of neurons. The specific timing of spikes or bursting events is also a way in which networks direct their output. In many contexts, to be useful to downstream targets, the neuronal output must be stable, resistant to perturbations or noise. From a mathematical viewpoint, this implies that the output is likely to be a stable periodic solution of a set of underlying equations that govern the network activity.

In order to have multiple functional roles, a network must have the ability to exhibit multiple stable outputs. There are two obvious ways in which this ability may arise. One is through neuromodulation, where different stable solutions exist for different parameter values or for different inputs to the network. The role of the modulator is to change parameter values between these states depending on the task to be completed. A second way is through multistability where more than one stable solution exists for the same set of parameter values. Which stable state ends up being the attracting solution depends on the initial conditions, i.e., the state at which the network becomes employed.

Short-term synaptic plasticity (STSP) refers to the ability of a synapse to change its synaptic strength depending on the frequency at which it is being activated by a presynaptic neuron. Facilitation refers to case where the strength is an increasing function of frequency and depression when it is a decreasing function. Significant research has been conducted to understand the mechanisms underlying plasticity. How STSP can shape the output of a neuronal network is also a central focus of investigation.

Just as there are synaptic rise and decay rates associated with different neurotransmitter receptor types, there are also different rates associated with facilitation or depression of a synapse. STSP acts at short timescales and, as a form of synaptic plasticity, is distinct from plasticity forms that act at long timescales: long-term potentiation and depression (LTP and LTD) and spike timing-dependent plasticity (STDP). LTP, LTD, and STDP last for very long time durations on the order of hours to weeks and are mainly associated with changes in synaptic strength due to the relative timing of firing in pre- and post-synaptic pairs. Timescales associated with STSP are on the order of several milliseconds to seconds, the same order as the rise and decay of excitatory, inhibitory, and typical voltage-gated ionic currents.

Below, we discuss a few basic models of STSP and provide some examples of how multiple stable solutions are created in small neuronal networks that involve STSP. Synapses that exhibit STSP have different steady-state amplitudes for different presynaptic firing rates. Multistability arises when the components of the network can be organized to access different values of these steady-state behaviors. This can occur through “fine-tuning” in predominantly feed-forward networks or through “self-consistency” in feedback settings. The role that STSP plays in creating these opportunities for multistability will be discussed below.

Mathematical Models of Short-Term Synaptic Depression

Three phenomenological models of short-term synaptic plasticity are reviewed. The first two, the AVSN model of Abbott et al. (1997) and the TM model (Tsodyks and Markram 1997), are the most popular and are generally used in conjunction with networks of spiking neurons. The third model, BMN (Bose et al. 2001), is relevant to neurons, such as bursters, that display slow oscillations and has the added feature that it separates the dynamics of synaptic plasticity from those of synaptic rise and decay.

For simplicity, we focus on models that only involve synaptic depression. In the Abbott et al. model, synaptic depression is based on the assumption that when a presynaptic spike results in transmission, the synaptic strength is decremented by some fraction f . Between spikes, the synapse recovers from depression. If $A(t)$ denotes the synaptic strength at time t and t_i denotes a sequence of spike times, then at each spike time

$$A(t_i^+) = fA(t_i^-),$$

where the superscript $+$ denotes limit from above and $-$ from below. Between spikes, the variable is allowed to recover according to

$$A' = (1 - A)/\tau_A$$

for time constant τ_A . If a set of presynaptic spikes arrives periodically with rate r , then the steady-state synaptic amplitude $A(r)$ can be calculated as

$$A(r) = \frac{1 - e^{-1/r\tau_A}}{1 - f e^{-1/r\tau_A}}. \quad (1)$$

In this model, the dynamics of depression and those of synaptic efficacy are both modeled by a single variable A .

The TM model describes synaptic plasticity by partitioning synaptic resources into three states: effective (E), inactive (I), and recovered (R), with $E + R + I = 1$. Each presynaptic spike at $t = t_{AP}$ utilizes a fraction U_{SE} of recovered resources transferring them to the effective pool. Resources in this group decay with time constant τ_{inact} to the inactive pool. From here, resources reenter the recovered pool with time constant τ_{rec} .

$$\begin{aligned} R' &= \frac{1}{\tau_{rec}} - U_{SE}R\delta(t - t_{AP}) \\ E' &= -\frac{E}{\tau_{inact}} + U_{SE}R\delta(t - t_{AP}). \end{aligned}$$

If action potentials arrive with interval Δt and if this time is large compared to τ_{inact} , then the postsynaptic current at each action potential can be calculated from

$$\begin{aligned} PSC_{n+1} &= PSC_n(1 - U_{SE})e^{-\Delta t/\tau_{rec}} \\ &+ A_{SE}U_{SE}\left(1 - e^{-\Delta t/\tau_{rec}}\right), \end{aligned} \quad (2)$$

where A_{SE} is the maximal PSC that can be produced if all resources immediately go from R to E . As with the AVSN model, the efficacy and time-scales associated with the synaptic current are modeled by the same set of variables that describe depression.

The BMN model is different than the above models in two ways. First, it dissociates the dynamics of plasticity from those of synaptic efficacy. Second, it is designed to model the effect of slow wave or bursting oscillations, not just spiking neurons. A variable d keeps track of the level of depression of the synapse, while the variable s transmits the synaptic efficacy. These variables are linked at $t = t_{sp}$ defined by the moment when the presynaptic voltage v increases through a threshold v_θ . Both are governed by first-order equations:

$$d' = \frac{1 - d}{\tau_a} H(v_\theta - v) - \frac{d}{\tau_\beta} H(v - v_\theta) \quad (3)$$

$$s' = \frac{d(t_{sp}) - s}{\tau_\gamma} H(v - v_\theta) - \frac{s}{\tau_\kappa} H(v_\theta - v), \quad (4)$$

where $H(x)$ is the Heaviside function equal to one when $x \geq 0$ and zero otherwise. The postsynaptic current generated by this model is simply $I_{syn} = \dot{g}_{syn}s(v - E_{syn})$ where $\dot{g}_{syn}$ and E_{syn} are the maximal conductance and reversal potential of the synapse. Figure 1 shows an example of how the s and d variables interact in the BMN model. Equations 3 and 4 are coupled only when the presynaptic neuron crosses v_θ at which point the value of s is allowed to evolve towards the value $d(t_{sp})$. If τ_γ is small, then this effectively serves as an instantaneous reset. Note that the dynamics of s then remains uncoupled from those of d until the next moment that v increases through threshold. In particular, when the presynaptic neuron is below threshold, the synaptic current decays with time constant τ_κ that is independent of the recovery of synaptic resources which is

Multistability Arising from Synaptic Dynamics, Fig. 1 The time trace of the d and s variables for the BMN model plotted in response to the presynaptic activity V_{pre} . The time constants that control depression (τ_β), recovery (τ_α) and decay (τ_κ) of the synapse are shown. s approaches the value of d at the onset of activity (d^* at steady state) with a fast time constant (τ_γ)

dependent on τ_α . If $A(t)$ from the AVSN model and the R variable from the TM model were plotted, they would qualitatively resemble the d variable of the BMN model (Fig. 1), except that, in the former two models, the variables would instantaneously be decremented at the time of a spike and recover between spikes, as opposed to the gradual decline over the time T_A in the BMN model. If a periodic train of presynaptic spikes or bursts with active time given by T_A and inactive time given by T_I drives Eqs. 3 and 4, then the steady-state amplitude for the synaptic resources, called d^* , measured at the time that v increases through v_θ is

$$d^* = \frac{1 - e^{-T_I/\tau_\alpha}}{1 - e^{-T_A/\tau_\beta} e^{-T_I/\tau_\alpha}}. \quad (5)$$

The peak synaptic strength g_{peak} can be calculated as the product of d^* with the maximal synaptic conductance

$$g_{peak} = \bar{g}_{syn} d^* \quad (6)$$

Note that for fixed T_A the expression for d^* is equivalent to that of $A(r)$ given in Eq. 1 in the AVSN model. Further, $T_I \rightarrow \infty$, $d^* \rightarrow 1$, monotonically showing that the level of available synaptic resources recovers back to a maximal value as the inactive time increases (equivalently as the frequency tends to 0).

Multistability Arising from Synaptic Dynamics, Fig. 2 For a depressing synapse, the peak synaptic strength is an increasing function of the presynaptic silent duration T_I as derived from Eqs. 5 and 6

All three models describe the short-term dynamics of a synapse when the presynaptic neuron is intrinsically rhythmic. In this case, the parameters r in the AVSN model, T_{AP} in the TM model, and T_I and T_A in the BMN model can be adjusted to achieve a specific synaptic strength. In particular, in a feed-forward or driven network, the level of plasticity can be finely tuned by controlling the frequency of the drive. In the case of a depressing synapse, strong drive leads to higher frequencies of synaptic usage, leading to weaker synapses. The opposite is true for lower-frequency driving. Figure 2 shows how the peak synaptic strength g_{peak} increases as a function of increasing T_I (T_A is kept fixed) for the BMN model. A qualitatively equivalent graph arises using Eq. 1 by plotting $A(r)$ versus $1/r$ or by using Eq. 2 to plot the steady-state PSC versus Δt . As the period increases (frequency decreases), the peak synaptic strength increases to the maximal level $\bar{g}_{syn}$.

In a feedback network containing many synapses with STSP, the quantities r , T_{AP} , T_I , and T_A do not necessarily remain parameters. Instead they can be affected by the synaptic inputs that the neuron receives. Thus to obtain periodic solutions, the plasticity variables must satisfy a consistency condition. Namely, network period is a function of synaptic strength and, alternatively, peak synaptic strength is a function of network

period. When these two are self-consistent, a periodic solution can occur. Multistability results when this consistency condition can be satisfied in different ways at different network periods.

Fine-Tuning Synaptic Strength in Feed-Forward Networks

In many central pattern-generating networks, the constituent neurons maintain a constant relative phase with respect to the network cycle even as the period of oscillations varies. To examine the role of STSP in such phase constancy, consider a network of two neurons O and F in which O is an oscillatory pacemaker neuron (with period P) which inhibits F and F rebounds from this inhibition to fire. After each inhibitory input to F , the time Δt that F takes to reach threshold can be determined. This defines a phase $\phi = \Delta t/P$ as the phase at which F fires. Manor et al. (2003) showed how synaptic depression could help the O – F network maintain phase. Namely, if O has small period, its synapse to F is depressed and thus weak. There is little effect on the timing Δt of F firing. In this case, there is a periodic solution in which the time to F firing is basically constant and controlled by parameters that are intrinsic to F . Alternatively, when the period of O is increased by increasing T_I , then its synapse to F has a chance to recover and become stronger. Now the firing time Δt depends more strongly on g_{peak} and the decay rate of inhibition τ_κ . This represents another stable solution where the phase of firing is controlled by the interplay of parameters associated with the O synapse and those intrinsic to F . In Manor et al. 2003, it is shown that Δt satisfies an equation of the form

$$c_1 e^{-\Delta t/\tau_w} + c_2 g_{\text{peak}} e^{-\Delta t/\tau_\kappa} = c_3. \quad (7)$$

for $c_1, c_2 > c_3 > 0$ and τ_w being a time constant associated with a potassium current in F . At small periods, g_{peak} is small and the first term in Eq. 7 dominates. As can be seen, Δt is independent of T_I , and therefore, $\phi = \Delta t/P \sim 1/P$. At larger periods, g_{peak} given in Eq. 6 increases with T_I and the second term dominates. In this case Δt

changes with P leading to a complicated dependence of phase with P [see (Manor et al. 2003) for the full details].

The main point to convey here is that, in a feed-forward network, if the peak synaptic strength is controlled by the pacemaker, then it can be effectively treated as a parameter. In particular, by controlling the period of the pacemaker, g_{peak} can be fine-tuned to any desired value leading to different kinds of solutions. Also see Carver et al. (2008) and Lewis and Maler (2002) where similar ideas are employed in a feed-forward context.

Self-Consistency in Feedback Networks

In Tsodyks et al. (2000), Tsodyks et al. showed how synaptic depression can be used to obtain population bursts in cortical excitatory-inhibitory (E – I) networks. Tabak et al. (2000) showed a similar result in a model of development of the chick spinal cord using a rate model that only involved excitation. Both models operate using similar principals. In the Tsodyks et al. study, a network of 400 E cells was mutually and randomly coupled to a set of 100 I cells. All synapses display both synaptic facilitation and depression of varying degrees. The effect of synaptic depression was more relevant, as facilitation plays less of a role in creating the population burst. Focusing solely on synaptic depression, if the E cells have a high firing rate, then their synapses weaken and have less effect on their postsynaptic targets. At lower frequencies, their synapses have a chance to recover so that, when they fire, they can strongly recruit other E and I cells into the population activity. In effect, the model utilizes the two distinct stable states (strong versus weak synapses) that are present in the feed-forward network described in the previous section, but now finds a way to internally toggle between the two. Figure 3 is from Tsodyks et al. (2000) in which the top panel shows the fraction of neurons that are active in a specified time bin and the bottom panel the time course of synaptic resource recovery from depression, averaged over all E cells. As the top panel shows, there are bursts of network activity where larger numbers of neurons are

Multistability Arising from Synaptic Dynamics, Fig. 3 Population bursts in a network model of E and I neurons coupled with dynamic synapses. *Top panel* shows network population activity. *Bottom panel* depicts the average synaptic resources for each E cell. (Modified from Tsodyks et al. 2000)

coactive. Correspondingly, associated with each burst is a rapid drop in the average synaptic resources, followed by recovery on a longer time-scale. Note that the recovery dynamics shown in the bottom panel corresponds to the trace of the d variable in Fig. 2 of the BMN model for the case where T_A is very short.

A critical reason that population bursts exist in the Tsodyks et al. model is the heterogeneity in the basal firing rates of the individual E cells. The network is tuned so that some fractions of E cells have high spontaneous firing rates. It is the firing of this group that initiates recruitment of other E cells that form the burst. Self-consistency then dictates that the level of available synaptic resources is sufficient to continue the recruitment of enough cells to form the burst. This will occur

only if the recruitment occurs after a suitably (and self-consistently) long inter-burst interval. See Tsodyks et al. (2000) for further details including how the existence of the burst depends on the maximal synaptic conductance.

In Bose et al. (2001), a simpler deterministic system consisting of just one E – I pair with depression in the I to E synapse is considered. Here, it is possible to mathematically analyze the self-consistency condition. In this model, the activity of I is slaved to that of E . A map $\Pi(d)$ is derived that measures the value of the depression variable each time E fires. This map is easily obtained by solving Eq. 3 over one complete cycle of a typically E oscillation. Namely, solve $d' = -d/\tau_\beta$ with initial condition $d(0)$ for a time T_A corresponding to how long E is active. Then solve $d' = (1 - d)/\tau_\alpha$ with initial condition $d(T_A)$ for a time T_I to find $d_{n+1} = \Pi(d_n)$ given by

$$d_{n+1} = 1 - \left(1 - d_n e^{-T_A/\tau_\beta}\right) e^{-T_I/\tau_\alpha}. \quad (8)$$

Consider the case where T_A is fixed, but T_I varies as a function of the synaptic strength of the I to E synapse. Because this synapse is frequency dependent, T_I is an unknown in Eq. 8. However, T_I can be determined at each cycle using an equation similar to Eq. 7 given by

$$c_1 e^{-T_I/\tau_w} + c_2 \bar{g}_{\text{inh}} d_n e^{-T_I/\tau_k} = c_3, \quad (9)$$

where $\bar{g}_{\text{inh}}$ is the maximal inhibitory conductance. A fixed point of the map Π corresponds to a periodic solution of the E – I network. The value of d at the fixed point, denoted d^* , determines the overall level of depression associated with that solution and correspondingly determines the network period. Note that d^* is still given by Eq. 5 and it represents the situation where there is a self-consistency between the network period ($T_I + T_A$) and synaptic strength (g_{peak}). As $\bar{g}_{\text{inh}}$ changes the fixed points of Π undergo two different saddle-node bifurcations leading to range of values over which there are two stable solutions shown in Fig. 4a. Along the lower stable branch of fixed points, the maximal synaptic strength is small and the ensuing I to E synapse never becomes strong

Multistability Arising from Synaptic Dynamics, Fig. 4 Bistability of a two-cell $E-I$ network where the I to E synapse is depressing. (a) The bifurcation diagram of network period versus the maximal conductance of the depressing synapse. Shaded region shows the bistable range. Solid lines are stable, dashed lines unstable. (b) Voltage traces of the two cells and the depression variable shown for a value of $\bar{g}_{inh}$ in the bistable range. A brief hyperpolarizing pulse in the I cell (arrow) results in a transition from the fast period oscillations [lower solid branch of (a)] to slow period oscillations [higher solid branch of (a)]. (Modified from Bose et al. 2001)

enough to slow the high-frequency intrinsic oscillations of E . Here, T_i is small and the value of the fixed point is small. On the upper branch, $\bar{g}_{inh}$ is large enough so that when I fires, it forces E to remain inactive for a longer time. This makes T_i become larger through Eq. 9, which through Eq. 5 forces d^* to become large. This leads to a low-frequency solution. In Bose et al. (2001), it is shown that both solutions can coexist leading to bistability. Figure 4b illustrates the bistability showing a voltage trace of an $E-I$ pair along

Multistability Arising from Synaptic Dynamics, Fig. 5 Two of multiple stable solutions in a network of one I neuron reciprocally coupled to four E neurons. The I to E synapse is depressing. (Modified from Chandrasekaran et al. 2009)

with the corresponding trace for d . At the beginning of the trace, $E-I$ oscillates at a high frequency in which the I to E synapse is depressed. Transient hyperpolarization of I allows its synapse to recover so that when it again fires, it can strongly inhibit E . The transition to longer periods then ensues. The transition back to high-frequency oscillations could occur, for example, by transiently driving E to higher frequencies (not shown). Thus, there are two coexistent stable solutions, and transient inputs can make the network transition between them.

In Chandrasekaran et al. (2009), the two-cell network is generalized to a globally inhibitory network consisting of a single I cell that is reciprocally coupled to a network of E cells. The E cells have no direct synaptic connections to one another. Each of the I cell synapses exhibits short-term depression. Similar to the previous example, I fires whenever any E cell fires. If the E cells are all synchronized, the I cell's firing rate will be low in comparison to when the E cells are clustered into different groups. As a result, the firing rate of I can be used as a proxy for determining how many clusters the E cells have broken into; see Fig. 5. The different firing rates of I yield different levels of depression which in turn can only exist if there is self-consistency with the exact number of clusters needed to produce the specific amount of depression. The generalization of equations and Eq. 9 to handle this case led to a

2-dimensional map for which there are multiple coexistent fixed points. Each fixed point corresponds to a solution with a different number of clusters of E cells. Full details are in Chandrasekaran et al. (2009), where it is shown that the firing rate of I has a one-to-one increasing relationship with the number of clusters. See also Bose and Booth (2011), which considers the role of synaptic depression in phase locking of two heterogeneous I cells.

General Observations Regarding Networks and Short-Term Synaptic Plasticity

Short-term synaptic plasticity has been suggested to be of importance for many functions in the nervous system. It has been proposed to play a role in cortical gain control (Abbott et al. 1997), population rhythm generation (Tabak et al. 2000; Tsodyks et al. 2000), and direction selectivity (Carver et al. 2008). In addition, temporal coding in cortical processing such as novelty detection, coincidence detection (Thomson 2000), sound localization (Cook et al. 2003), and phase maintenance (Manor et al. 2003) may be attributed to depression. In experimental (Manor and Nadim 2001) studies of invertebrate central pattern generators, synaptic depression has been shown to introduce bistability of firing patterns. In Izhikevich et al. (2003), it is proposed that STSP creates a synaptic resonance whereby networks align themselves to operate at frequencies where there is a balance between synaptic facilitation and depression. That work suggests that by operating at resonant frequencies, networks increase the reliability of synaptic transmission and provide a novel mechanism for selective communication between neurons.

A specific proposed role of synaptic plasticity is that it gives rise to multistability or the existence of multiple different stable states. Multistability is defined as the coexistence of different stable states for the same parameter values. Alternatively, networks can have different stable states as a result of changing of parameter values due to neuromodulation or external drives to the

network. These two situations give rise to distinct types of networks, predominantly feedback versus feed-forward. Furthermore, they lead to different kinds of mathematical questions and challenges.

In studying networks involving STSP, the underlying intrinsic dynamics of individual neurons are relevant, but often only in how they affect the synapses. Indeed, an important point to note is that there are effects of plasticity that are independent of the properties of the postsynaptic cell. This is especially true in feed-forward networks where the level of plasticity, as argued above, can be fine-tuned. One can then assess how the level of fine-tuning affects different kinds of model cells. The fine-tuning itself is just a synaptic property. Where the interplay between synapse and cell model can become important is in feedback networks, where the postsynaptic cell has to transform the synaptic input it receives into a synaptic output. If the outgoing synapse itself exhibits plasticity, then how the intrinsic properties of the cell interact with the incoming synaptic properties would quantitatively affect the output of the system. However, the qualitative behavior of the network, including the existence of multistability, would be less affected by these intrinsic properties.

There are several mathematical challenges that arise in assessing whether multistability arises due to synaptic plasticity. In the absence of plasticity, when the synaptic coupling is not frequency dependent, then it is often possible to derive a 1-dimensional map to assess the existence and stability of solutions. Further, when the coupling between neurons is weak, then averaging can be used to derive a simplified 1-dimensional equation based on phase differences to assess these questions (Ermentrout and Kopell 1991). Synaptic plasticity, by its nature, does not lead to weak coupling. The maps in this case are typically 2 dimensional or higher. While the analysis of these higher-dimensional maps poses significant mathematical challenges, it also affords the opportunity to derive new mathematical techniques for their analysis that can be generalized to other scenarios.

Definition

Multistability in Perception Dynamics is the phenomenon of spontaneous switching in the subject’s perception between different interpretations of an ambiguous sensory stimulus.

Detailed Description

When subjects are confronted with an ambiguous sensory stimulus for an extended time, instead of experiencing a fixed percept, they report spontaneous switching between the different interpretations, a phenomenon known as perceptual multistability.

In perceptual multistability, while the subject is aware of one percept, the others appear suppressed from consciousness. Moreover, the subject experiences constant switches from being aware to being unaware of a given percept. This phenomenon is thought to provide a powerful method to search for neural correlates of conscious awareness, since it allows to disentangle the neural response related to the physical properties of the stimulus, which is continuously present, from that related to the conscious percept (Rees et al. 2002; Sterzer et al. 2009).

Perceptual multistability, and especially perceptual bistability (two interpretations), has been extensively studied in the visual modality (see Leopold and Logothetis 1999; Blake and Logothetis 2002; Tong et al. 2006 for reviews). The paradigmatic example of perceptual multistability in the visual system is the so-called binocular rivalry, for which there exists a vast literature (see, for instance, Blake 1989; Tong and Engel 2001). In binocular rivalry two drastically different images (face and house, for instance; see Fig. 1a) are presented to the two eyes simultaneously, and perception alternates between these two images. Other examples of perceptual bistability in the visual system include the Necker cube (alternation of two depth organizations; Fig. 1b), Rubin's vase-face (alternation of two figure-ground organizations; Fig. 1c), bistable apparent motion (alternation of two

arrangements of moving objects, Wallach 1935; Hupé and Rubin 2003; Rubin and Hupé 2004; see http://cerco.ups-tlse.fr/~hupe/plaid_demo/demo_plaids.html for a demonstration), etc.

Typically associated to the visual system, multistable perception has been reported in other sensory systems: auditory (Deutsch 1974; Pressnitzer and Hupé 2006; Bregman 1990), olfactory (Zhou and Chen 2009), and tactile (Carter et al. 2008). Recent studies suggest some common characteristics of perceptual multistability (Leopold and Logothetis 1999) across sensory modalities (Pressnitzer and Hupé 2006; see also Schwartz et al. 2012; Denham et al. 2012), namely:

- **Exclusivity.** Conflicting visual representations are not simultaneously present.
- **Inevitability.** Given sufficient time, switching will ultimately occur. Some factors such as attention (van Ee et al. 2005; Meng and Tong 2004) and strong intrinsic or extrinsic biases towards one of the percepts (Lack 1978; Moreno-Bote et al. 2010) can slow switching down but do not eliminate it.
- **Randomness.** Durations of perceptual bouts follow log-normal (or gamma) distributions (Levelt 1968; Lehky 1995; Logothetis et al. 1996; Brascamp et al. 2005). Correlations between durations of successive perceptual bouts are absent or insignificant (Lehky 1995; Logothetis et al. 1996; Pastukhov and Braun 2011).

Multistability in Perception Dynamics, Fig. 1 Examples of visually ambiguous patterns (a) Face-house rival image created by Frank Tong and used in his fMRI study of binocular rivalry (reproduced from Tong et al. 1998 with permission from Elsevier); when viewed with *green-red* 3D glasses, perception alternates

between a house and a face. (b) Necker cube; it can be perceived as a cube with the *lower-left* face or the *upper-right* face in front. (c) Rubin's face-vase; it can be perceived as a white vase or the silhouette of two black faces. Figures (b) and (c) from wikimedia commons

Since alternations occur not only when the inputs to the competing percepts are equal but also when they are largely unbalanced, one can study how changes in the stimulus' parameters affect perceptual dominance durations. For the domain of binocular rivalry, Levelt introduced a set of four "propositions" that summarize the effects of stimulus contrast of the monocular images on the switching dynamics (Levelt 1968). These properties, which are based on experimental observations, have been object of study in several works on perceptual bistability. Based on the existing literature, there is a general agreement on the reformulation of the second proposition. Thus, Levelt's updated set of binocular rivalry propositions state that:

- (I) Increasing the stimulus strength in one eye will increase the predominance of the stimulus.
- (II) Increasing the stimulus strength in one eye will affect the mean dominance duration of the eye with highest contrast (Brascamp et al. 2006; Boxtel et al. 2007; Klink et al. 2008; Moreno-Bote et al. 2010).
- (III) Increasing the stimulus strength in one eye will increase the alternation rate.
- (IV) Increasing the stimulus strength in both eyes will increase the alternation rate.

Although these propositions were originally described for the domain of binocular rivalry, dynamic properties for some stimulus manipulations in other bistable paradigms also satisfy them (Rubin and Hupé 2004; van Ee 2005; Klink et al. 2008; Moreno-Bote et al. 2010).

Neural Correlates of Perception

Experimental results in the visual system for subjects experiencing rivalry – imaging in humans and electrophysiology in awake, behaving monkeys – have revealed traces of neural activity that correlates with subject's perception at anatomically lower areas of visual processing (Tong and Engel 2001; Polonsky et al. 2000; Parkkonen et al. 2008), higher areas of visual processing (Leopold

and Logothetis 1996; Tong et al. 1998; Leopold and Logothetis 1999; Sheinberg and Logothetis 1997), as well as nonvisual parietal and frontal areas (Sterzer and Kleinschmidt 2007). Moreover, monkey electrophysiology (Leopold and Logothetis 1996) revealed that the proportion of neurons firing in time with perception increases along the visual pathway. Thus, while evidence of alternations is seen in different brain areas, the origin, which may involve interacting multiple areas, is still unknown.

Perceptual Multistability in Different Sensory Modalities: Auditory Streaming

Perceptual multistability has been extensively studied in the visual system. However, multistable perception has been reported in other sensory systems, in particular in the auditory system (see Schwartz et al. 2012 for a short review). Examples of multistability in the auditory system are found in binaural rivalry (Deutsch 1974), in the verbal transformation effect observed during word repetition (Warren and Gregory 1958; Warren 1961) and, especially, in the *auditory streaming* paradigm (Pressnitzer and Hupé 2006; Schnupp et al. 2010).

For the auditory streaming paradigm, the stimulus consists of a high-frequency tone A and a low-frequency tone B that are played alternately (AB-AB pattern) or in triplets (ABA-ABA pattern). For a slow presentation rate, the melody is perceived as a single stream that resembles a galloping (for the triplet pattern). However, if the presentation rate is fast enough and the frequency separation between the two tones is large enough, the melody is perceived as two separate streams (A-A-A-A and B-B-B-B). For intermediate values, there is ambiguity between coherence (a single stream) and segregation (two streams). These perceptual states were first reported by van Noorden in the so-called van Noorden diagram (van Noorden 1975). See Fig. 2. Later, experiments with long presentations reported alternations between these two states in the ambiguous region (Pressnitzer and Hupé 2006). Visit <http://auditoryneuroscience.com/topics/streaming-galloping-rhythm-paradigm>

and <http://auditoryneuroscience.com/topics/streaming-alternating-tones> for a demonstration that illustrates auditory streaming.

As in visual multistability, perceptual correlations of neural activity have been observed in different brain areas. Recent studies indicate that perceptual auditory object formation, or “streaming,” may be based on neural activity within the auditory cortex and beyond (Cusack 2005; Micheyl et al. 2005), as well as in early stages of the auditory pathway, such as the cochlear nucleus (Pressnitzer et al. 2008).

Some models have been developed for the auditory streaming paradigm (Almonte et al. 2005; Wang and Chang 2008; Mill et al. 2013). However, most of them try to account for the van Noorden diagram (see Fig. 2), rather than the dynamics of perceptual switches reported for parameters in the ambiguous region of the diagram (Pressnitzer and Hupé 2006).

Computational Models for Perceptual Switches

Current models of perceptual multistability are mainly phenomenological and try to explain the

Multistability in Perception Dynamics, Fig. 2 Van Noorden diagram for the auditory streaming paradigm. (Reproduced from McAdams and Bregman 1979 and adapted from Van Noorden (1975) with permission from the author)

dynamics of perceptual switching with simple computational mechanisms. They mainly focus on visual bistable stimuli (just two competing interpretations) and especially on binocular rivalry. Among representative firing rate models, we find Lehky (1988); Mueller (1990); Wilson (2003); Laing and Chow (2002); Moreno-Bote, Rinzel, and Rubin (2007); and Kilpatrick and Bressloff (2010). While details vary among models, the mechanism underlying the alternating rhythmic behavior is similar. It involves competition between two neural populations coding for the competing percepts via reciprocal inhibition (the neurons generating the dominant percept inhibit the neurons coding the suppressed percept) and slow negative feedback in the form of spike-frequency adaptation and/or synaptic depression (over time the system fatigues allowing the suppressed percept to become dominant). See Fig. 3. Noise is added to the system to account for the irregular oscillations and, in some cases, to drive the switches, causing adaptation to play a secondary role (Kim et al. 2006; Brascamp et al. 2006; Moreno-Bote et al. 2007). These models do not usually specify the site at which these competing neural populations are located.

This framework (competition with mutual inhibition and adaptation) is, in principle, that of the half-center oscillator in models for central pattern generators, networks that drive opposing muscles for locomotion, respiration, swallowing, etc. (Hooper 2001; Brown 1914).

Multistability in Perception Dynamics, Fig. 3 Schematic representation of the network architecture consisting of two mutually inhibitory populations that code for the two competing percepts. In addition to the mutual inhibitory connections (represented by *solid lines*), neural populations receive excitatory synaptic input of strength I_i associated to the external stimuli and undergo self-adaptation (indicated by the *dashed* connections)

Mathematical Formulation

The firing rate models developed for perceptual multistability try to capture the qualitative aspects of the behavioral data with idealized models that avoid the overhead of detailed cell-based models. They assume that the relevant information is captured by the firing rate of each neural population. The mathematical formulation for the firing rate or activation dynamics r_i of the i -population (responsive to percept i) can be described by

$$\begin{aligned}\tau \frac{dr_i}{dt} &= -r_i + f_i \left(\sum_j w_{ij} s_j r_j - \gamma a_i + I_i + n_i \right) \\ \tau_a \frac{da_i}{dt} &= -a_i + r_i \\ \tau_s \frac{ds_i}{dt} &= 1 - s_i + \phi s_i r_i\end{aligned}\quad (1)$$

where I_i is the direct stimulus input, w_{ij} is the strength of the synaptic currents to population i generated by the rates r_j of the other competing populations j , a_i is the spike-frequency adaptation of population i (subtractive negative feedback), and s_j is the variable controlling synaptic depression of the synapses from population j (divisive negative feedback). The parameters γ and ϕ control the strength of spike-frequency adaptation and synaptic depression, respectively. The time scales for the slow self-adaptation τ_a (subtractive) and τ_s (divisive) are much larger than the time scale τ for the activation dynamics r_i of population i . Population's gain function f_i describes the steady-state output firing rate for constant input. It is usually assumed to be non-negative and monotonically increasing, typically taken to be a Heaviside, piecewise linear, or sigmoid function. Gaussian white noise or colored noise n_i is added to the differential equations for the neural responses r_i .

Parameters are tuned so that the models account for many features of the empirical data of the alternations (distributions of dominance durations, lack of correlations, etc.) and satisfy to some extent Levelt's propositions for stimulus parameter variations corresponding to binocular rivalry and other bistable phenomena.

What Drives the Switches? Adaptation Versus Noise; Oscillatory Versus Winner-Take-All Models

Schematically, the dynamics of switches for model Eq. 1 can be represented by a double-well-potential-type architecture coupled with noise (Brascamp et al. 2006; Kim et al. 2006; Moreno-Bote et al. 2007). The two perceptual states are represented by two wells and the current state is represented by the position of a ball within these wells (see Fig. 4). The ball initially settles into one of these wells. If adaptation is not present in the system, the depth of the wells will remain unchanged and the noise fluctuations will eventually kick the ball from the occupied well to the other one. See Fig. 4a. In Fig. 5a we show the time course of the activity of the two populations. But if adaptation is present, the wells will slowly change, depth decreasing for the well where the ball is located and then recovering when the ball is absent. If adaptation is strong enough, it will eventually destroy the energy minimum and form a single well potential; the ball will roll towards the other well. See Fig. 4b. In Fig. 5b we show for the time course of the population activity and the adaptation. However, if adaptation is weak, it will only reduce the depth of the well but without destroying the local minimum. As in the adaptation-free case, the noise will be the ultimate responsible of kicking the ball to the other well. See Fig. 4c. In Fig. 5c we show the time course of the population activity and the adaptation.

Thus, one can distinguish between *oscillatory models* (slow adaptation causes alternations by itself) and *noise-driven attractor models* (noise drives switches in a winner-take-all framework). For noise-driven attractor models, the deterministic system (without noise) has two stable fixed points (attractors) (Figs. 4a and 5a). Such a system may incorporate adaptation, as long as it is weak enough so that it does not destroy the stable fixed points (Figs. 4c and 5c). For those models, if noise is removed, the system will remain indefinitely in one of the attractors. For oscillatory models the deterministic system does not have stable fixed

Double well potential landscape for three models of perceptual bistability: (b), (a) noise-driven model without adaptation, adaptation-driven model, and (c) noise-driven model with weak adaptation. The position of the ball represents the perceptual state at a given moment. Adaptation slowly modulates the potential landscape

model without adaptation, adaptation-driven model (c), and noise-driven model with weak adaptation

points but a stable limit cycle, with most of the time spent in the wells (Figs. 4b and 5b). For such a system, noise can be incorporated (e.g., to account for the variability in the dominance durations) as long as it does not destroy the limit cycle. To assess the role of noise and adaptation, the models try to conform to experimental data on dominance durations (averages, histograms' shape, correlations

between successive durations, etc.) and Levelt's propositions. Several studies suggest that models should operate in the noise-driven regime but not far from the boundary of being adaptation driven (Moreno-Bote et al. 2007; Shpiro et al. 2009; Pastukhov et al. 2013; Huguet et al. 2014).

Indeed, for white noise-driven attractor models, the residence times in each state will be

exponentially distributed; switching is a Poisson process, described by Kramer's rate theory (Kramers 1940). For adaptation-driven oscillator models, the residence times are regular, and adding noise will only perturb them around the mean; the distributions will look symmetrical around the mean. If adaptation is weakened, effectively giving more strength to noise, the histogram gradually evolves into a skewed one (log-normal or gamma as observed in the experiments). Thus, noise-driven models provide more variability and weak adaptation precludes short perceptual durations. In the double-well framework, the ball must wait for adaptation to adequately reduce the barrier before leaving the well, thus preventing the ball from leaving immediately after settling into the well.
